vap.	= vapour

In the **cross references** the first number in clarendon type is the number of the volume; the second number refers to the chapter; and the succeeding number refers to the "§," section. Thus 5. 38, 24 refers to § 24, chapter 38, volume 5.

The oxides, hydrides, halides, sulphides, sulphates, carbonates, nitrates, and phosphates are considered with the basic elements; the other compounds are taken in connection with the acidic element. The double or complex salts in connection with a given element include those associated with elements previously discussed. The carbides, silicides, titanides, phosphides, arsenides, etc., are considered in connection with carbon, silicon, titanium, etc. The intermetallic compounds of a given element include those associated with elements previously considered.

The use of **triangular diagrams** for representing the properties of three-component systems was suggested by G. G. Stokes (*Proc. Roy. Soc.*, 49. 174, 1891). The method was immediately taken up in many directions and it has proved of great value. With practice it becomes as useful for representing the properties of ternary mixtures as squared paper is for binary mixtures. The principle of triangular diagrams is based on the fact that in an equilateral triangle the sum of the perpendicular distances of any point from the three sides is a constant. Given any three substances *A*, *B*, and *C*, the composition of any possible combination of these can be represented by a point in or on the triangle. The apices of the

triangle represent the single components *A*, *B*, and *C*, the sides of the triangle represent binary mixtures of *A* and *B*, *B* and *C*, or *C* and *A*; and points within the triangle, ternary mixtures. The compositions of the mixtures can be represented in percentages, or referred to unity, 10, etc. In Fig. 1, pure *A* will be represented by a point at the apex marked *A*. If 100 be the

FIG. 1.

FIG. 2.

FIG. 3.

standard of reference, the point *A* represents 100 per cent. of *A* and nothing else; mixtures containing 80 per cent. of *A* are represented by a point on the line 88, 60 per cent. of *A* by a point on the line 66, etc. Similarly with *B* and *C*—Figs. 3 and 2 respectively. Combine Figs. 1, 2, and 3 into one diagram by superposition, and Fig. 4 results. Any point in this

FIG. 4.—Standard Reference. Triangle.

diagram, Fig. 4, thus represents a ternary mixture. For instance, the point *M* represents a mixture containing 20 per cent. of *A*, 20 per cent. of *B*, and 60 per cent. of *C*.

CHAPTER LXVI (*continued*)

IRON (*continued*)

§ 35. The Iron Fluorides

IN 1771, C. W. Scheele¹ dissolved iron in hydrofluoric acid but he did not obtain well-defined crystals from the soln., owing to impurities which were introduced by the action of the acid on the glass containing vessel. H. Moissan, and O. Ruff and E. Ascher observed the conditions under which fluorine attacks iron, and the iron oxides. C. Poulenc found that when iron, or anhydrous ferrous chloride is heated to redness in a current of dry hydrogen fluoride, colourless, monoclinic crystals of **ferrous fluoride**, FeF_2 , are formed. The anhydrous salt was also obtained by J. J. Berzelius, and A. Scheurer-Kestner, by heating the hydrated salt out of contact with air, or better, in a current of dry hydrogen fluoride. The product obtained by A. Ferrari by heating the hydrated salt in hydrogen did not appear crystalline when examined by the X-radiogram process, but after heating the residue with ammonium fluoride in hydrogen, crystals were developed. L. Hackspill and R. Grandadam obtained it by heating iron with sodium fluoride: $\text{Fe} + 2\text{NaF} = \text{FeF}_2 + 2\text{Na}$; and O. Ruff and E. Ascher, by heating ferric fluoride above 400° , or by reducing it with iron, ammonia, sulphur dioxide, or hydrogen.

A. Scheurer-Kestner obtained green, prismatic crystals of the *octohydrate*, $\text{FeF}_2 \cdot 8\text{H}_2\text{O}$, by evaporating for some days the green soln. obtained by dissolving iron in hydrofluoric acid of sp. gr. 1.07. J. L. Gay Lussac and L. J. Thénard, and J. J. Berzelius, under similar conditions, obtained the *tetrahydrate*, $\text{FeF}_2 \cdot 4\text{H}_2\text{O}$; and C. Poulenc showed that the tetrahydrate is formed when the soln. containing only a little acid, is evaporated at ordinary temp. W. Biltz and E. Rahlfs observed that the addition of alcohol to the aq. soln. precipitates the tetrahydrate.

O. Ruff and E. Ascher said that the anhydrous salt is white. A. Scheurer-Kestner described the crystals of the anhydrous salt as small, yellow, quadratic prisms; and C. Poulenc, as transparent, lustrous, branching, monoclinic prisms. C. Poulenc observed that the tetrahydrate forms white, rhombohedral crystals. According to V. M. Goldschmidt, the X-radiograms show that the crystals of the anhydrous salt are tetragonal of the rutile type, like those of the anhydrous fluorides of magnesium, zinc, manganese, cobalt and nickel. The lattice dimensions are $a = 3.83 \text{ \AA}$., and $c = 3.36$, so that $a : c = 1 : 0.69$; and the distance between the iron and fluorine atoms is about 2.11 \AA . A. Ferrari gave $a = 4.670 \text{ \AA}$., $c = 3.297$, and $a : c = 1 : 0.706$. C. Poulenc gave 4.09 for the sp. gr. of the anhydrous salt; and W. Biltz and E. Rahlfs, 4.09 at $25^\circ/4^\circ$. A. Ferrari calculated 4.333 from the lattice constants, and O. Ruff and E. Ascher, 3.95. O. Ruff and E. Ascher gave 22.9 for the mol. vol.; and V. M. Goldschmidt, and J. W. Grüner calculated values for the atomic radius of anion and cation. W. Biltz and E. Rahlfs gave 2.095 at $20^\circ/4^\circ$ for the sp. gr. of the tetrahydrate, and 79.19 for the mol. vol.

C. Poulenc said that the anhydrous salt volatilizes at 1100° . K. Jellinek and A. Rudat noted that the salt is solid at 700° ; and W. Biltz and E. Rahlfs estimated that the m.p. exceeds 1000° . A. Ferrari discussed the relation between the m.p. and the space-lattice. For the dehydration of the hydrate, *vide supra*. K. Jellinek and A. Rudat gave the vap. press., p , of the fluorine at 773° K ., 873° K ., and 973° K ., $p = -\log 40.05$, $-\log 35.14$, and $-\log 31.06$ respectively; and they calculated the heat of formation to be $(\text{Fe}, \text{F}_2) = 154.2 \text{ Cals.}$; O. Ruff and E. Ascher, and H. von

Wartenberg gave $(\text{Fe}, \text{F}_2, \text{Aq.}) = 177.2$ Cals.; E. Petersen gave $2\text{AgF} \cdot \text{Aq.} + \text{FeCl}_2 \cdot \text{Aq.} = 2\text{AgCl} + \text{FeF}_2 \cdot \text{Aq.} + 31.8$ Cals., or $\text{Fe}(\text{OH})_2 + 2\text{HF} \cdot \text{Aq.} = \text{FeF}_2 \cdot \text{Aq.} + 26.6$ Cals.; and M. Berthelot gave $(\text{Fe}, \text{F}_2, \text{Aq.}) = 127$ Cals. G. Beck discussed the free energy of the salt. R. Peters observed that ferrous fluoride in aq. soln. is probably as strongly ionized as is ferrous chloride since the electrical conductivity of a mixed soln. of ferrous chloride and sodium fluoride does not deviate much from the value calculated from the mixture rule; and similarly also for the lowering of the f.p. of these soln.

C. Poulenc observed that at a dull red-heat, ferrous fluoride is partially reduced by *hydrogen*, and at a higher temp. the reduction is complete. K. Jellinek and A. Rudat found the equilibrium values for the reaction: $\text{FeF}_2 + \text{H}_2 \rightleftharpoons 2\text{HF} + \text{Fe}$, $\log (P_{\text{HF}}^2/P_{\text{H}_2})$ for 500° , 600° , and 700° are respectively -2.78 , -2.02 , and -1.23 . For the direct reduction, and the reverse reaction, with p vol. per cent. of hydrogen fluoride in the gaseous phase:

	$\text{FeF}_2 + \text{H}_2 \rightleftharpoons 2\text{HF} + \text{Fe}$			$\text{Fe} + 2\text{HF} \rightleftharpoons \text{FeF}_2 + \text{H}_2$	
$T^\circ \text{ K.}$	773°	873°	973°	773°	973°
p	4.0	9.3	21.5	4.7	21.3

The reduction of ferrous fluoride by hydrogen is an endothermic reaction. H. Schulze said that the anhydrous fluoride at a red-heat is not attacked by *oxygen*, but C. Poulenc observed that the anhydrous salt furnishes ferric oxide when heated in *air* or in *water* vapour. The salt dissolves slowly and sparingly in water, and the salt in aq. soln. is readily hydrolyzed with the deposition of hydrated ferric oxide. J. J. Berzelius, A. Scheurer-Kestner, and C. Poulenc observed that the hydrated salt decomposes when it is heated in air, forming ferric oxide, and this oxide is also produced when the hydrated salt is heated in hydrogen at 80° , but at a higher temp., it is reduced to iron. J. L. Gay Lussac and L. J. Thénard, J. J. Berzelius, and C. Poulenc added that the hydrated salt also dissolves sparingly in water; and that if hydrofluoric acid be present the salt is more readily dissolved than it is in water alone.

F. Fichter and A. Goldach studied the oxidation of ferrous fluoride by *fluorine*. O. Ruff and E. Ascher found that neither *bromine* nor *iodine* has any perceptible action on ferrous fluoride. G. Gore found that anhydrous ferric fluoride is neither attacked nor dissolved by liquefied *hydrogen fluoride*; and C. Poulenc found that in hydrogen fluoride at 1100° , crystals of ferrous fluoride are formed. The anhydrous salt and the hydrate dissolve in *hydrofluoric acid*—*vide supra*—more readily than they do in water, and the aq. soln. when treated with potassium permanganate, or exposed to air, forms ferric fluoride. A. Scheurer-Kestner observed that a soln. of ferrous fluoride in an excess of hydrofluoric acid forms ferric fluoride. When the fluoride is heated in *hydrogen chloride*, O. Ruff and E. Ascher observed that ferrous chloride is formed, but, at ordinary temp., ferrous chloride is converted into the fluoride: $\text{FeF}_2 + 2\text{HCl} \rightleftharpoons \text{FeCl}_2 + 2\text{HF}$. The anhydrous salt is attacked with difficulty by conc. *hydrochloric acid*; but C. Poulenc said that the hydrated salt is readily dissolved by this acid.

O. Ruff and E. Ascher observed that anhydrous ferrous fluoride does not react with *sulphur* to any great extent; if the product be treated with dil. hydrochloric acid, traces of hydrogen sulphide are formed. C. Poulenc observed that when heated with *hydrogen sulphide*, ferrous fluoride forms ferrous sulphide; O. Ruff and E. Ascher, that at a red-heat, *sulphur dioxide* only deepens the colour of the salt; and C. Poulenc, that when heated with conc. *sulphuric acid* ferric sulphate is formed. The tetrahydrate is readily soluble in sulphuric acid. O. Ruff and E. Ascher found that ferrous fluoride is slowly decomposed by *ammonia* at a dull red-heat, but, according to W. Biltz and E. Rahlfs, the tetrahydrate forms with liquid ammonia at -78.5° , or gaseous ammonia at 0° , **ferrous aquopentammino-fluoride**, $\text{FeF}_2 \cdot 5\text{NH}_3 \cdot \text{H}_2\text{O}$, which, at -21° , -11° , and 0° , has a heat of formation of 9.8 Cals., and the dissociation press. respectively 24, 51, and 113 mm. The sp. gr. is 1.477 at -21° , and the mol. vol. 133.4. Above 0° , this salt passes into

ferrous aquoamminofluoride, $\text{FeF}_2 \cdot \text{NH}_3 \cdot \text{H}_2\text{O}$, which at 25° , 34.5° , 46.5° , and 61.0° , has a heat of formation of 12.4 Cals.; and dissociation press. respectively 9.5, 18.6, 40.5, and 96.0 mm. The sp. gr. is 2.321 at 25° , and the mol. vol., 55.53. Above 25° , this salt furnishes **ferrous aquohemiamminofluoride**, $\text{FeF}_2 \cdot \frac{1}{2} \text{NH}_3 \cdot \text{H}_2\text{O}$. O. Ruff and E. Ascher observed that conc. *nitric acid* decomposes ferrous fluoride in the cold with the evolution of brown vapours, and the formation of a ferric salt. C. Poulenc noted that the tetrahydrate dissolves in nitric acid, forming ferric fluoride and nitrate. O. Ruff and E. Ascher found that *phosphorus*, and *arsenic* have no perceptible action on ferrous fluoride.

According to O. Ruff and E. Ascher, *carbon* has no appreciable action on ferrous fluoride. C. Poulenc observed that ferrous fluoride is insoluble in *alcohol*, and *ether*, but if water be present, the salt may be dissolved, so that the tetrahydrate dissolves in these menstrua. The salt is readily oxidized under these conditions. Ferrous fluoride is insoluble in *benzene* and it is but slightly attacked when boiled with 20 per cent. *acetic acid*. O. Ruff and E. Ascher found that when it is heated with crystalline *silicon*, ferrous fluoride is vigorously decomposed. The complex with *silicon tetrafluoride* is the so-called **ferrous fluosilicate**, FeSiF_6 , (*q.v.*); that with *titanium tetrafluoride* is R. Weber's **ferrous fluotitanate**, $\text{FeTiF}_6 \cdot 6\text{H}_2\text{O}$; and that with *boron trifluoride* and antipyrine is E. Wilke-Dörfurt and H. G. Murek's **ferrous hexantipyrinoborofluoride**, $[\text{Fe}(\text{COC}_{10}\text{H}_{12}\text{N}_2)_6](\text{BF}_4)_2$. O. Ruff and E. Ascher found that ferrous fluoride reacts with incandescence when it is heated with *sodium*; *copper* has no perceptible action; *magnesium* reacts explosively; *zinc* reacts with a strong evolution of heat; *aluminium* reacts with a feeble detonation; *iron* has no perceptible action; a boiling 33 per cent. soln. of *sodium hydroxide* forms some sodium fluoride, but the soln. remains colourless; and fused *sodium carbonate* furnishes ferric oxide and sodium fluoride.

J. J. Berzelius, A. Scheurer-Kestner, P. Barteczko, J. C. G. de Marignac, E. Deussen, H. Kessler, and R. F. Weinland and O. Köppen reported a number of complex salts formed by ferrous fluoride. R. Wagner obtained **ammonium ferrous trifluoride**, or *ammonium trifluoerrite*, $\text{NH}_4\text{FeF}_3 \cdot 2\text{H}_2\text{O}$, in green octahedra, and **ammonium ferrous tetrafluoride**, or *ammonium tetrafluoerrite*, $(\text{NH}_4)_2\text{FeF}_4$, in brown crystals. R. Wagner could not prepare the anhydrous **potassium ferrous trifluoride**, KFeF_3 , said by J. J. Berzelius to be precipitated in pale green crystals when a soln. of ferrous sulphate is added to one of potassium fluoride, instead, he obtained flesh-coloured potassium ferrous trifluoride, or *potassium trifluoerrite*, $\text{KFeF}_3 \cdot 2\text{H}_2\text{O}$. N. N. Ray prepared **ferrous fluoberyllate**, $\text{FeBeF}_4 \cdot 7\text{H}_2\text{O}$, by evaporating on the water-bath a soln. of iron and beryllium oxides in hydrofluoric acid. The salt is also obtained by the action of ferrous chloride on silver fluoberyllate, and adding alcohol to the filtered liquid. The pale green crystals of the *heptahydrate* have a sp. gr. 1.894 at $30^\circ/4^\circ$, and a mol. vol. of 140.95. The salt loses 4 mols. of water over conc. sulphuric acid. The **potassium ferrous tetrafluoride**, or *potassium tetrafluoerrite*, K_2FeF_6 , has also been prepared. According to R. F. Weinland and O. Köppen, when hydrofluoric acid soln. of ferrous and aluminium fluorides are mixed, and concentrated over lime at ordinary temp., small greenish-white crystals of **aluminium ferrous fluoride**, or *aluminium fluoerrite*, $\text{AlF}_3 \cdot \text{FeF}_2 \cdot 7\text{H}_2\text{O}$, are formed.

C. W. Scheele² dissolved ferric oxide in hydrofluoric acid, but did not get a well crystallized product from the soln. because of impurities introduced by the action of the acid on the glass. H. St. C. Deville prepared **ferric fluoride**, FeF_3 , by treating calcined ferric oxide with warm, conc. hydrofluoric acid, evaporating the soln. in a platinum crucible, and heating the residue until the bottom of the crucible was white-hot. There collected in the upper part of the crucible a partially-fused sublimate of colourless or greenish crystals of ferric fluoride. C. Poulenc obtained the anhydrous fluoride, in small green crystals, by passing hydrogen fluoride over red-hot iron, ferric oxide, or ferric chloride, or, by heating ammonium ferric fluoride in an inert gas—say nitrogen. O. Ruff, and O. Ruff

and E. Ascher obtained the fluoride by the action of fluorine on iron, or on ferric chloride.

A. Scheurer-Kestner, E. Deussen, and R. Peters obtained a soln. of ferric fluoride by the action of an excess of hydrofluoric acid, or of nitric acid on a soln. of ferrous fluoride in hydrofluoric acid; J. J. Berzelius, E. Deussen, G. Gallo, H. St. C. Deville, and A. W. Speransky, by dissolving ferrous hydroxide or ferric oxide in hydrofluoric acid. The evaporation of the aq. soln. furnishes flesh-coloured or colourless crystals of the hydrated fluoride. According to E. Deussen, H. Kessler, and A. Loesche, the action of hydrofluoric acid on ferric oxide is to be symbolized: $2\text{Fe}_2\text{O}_3 + 8\text{HF} = \text{FeO} + \text{H}_2\text{O}_2 + 3\text{H}_2\text{O} + \text{FeF}_3 \cdot \text{FeF}_3 \cdot \text{FeF}_2$, and on evaporating the soln., crystals of *ferrous fluoferite*, $\text{Fe}_3\text{F}_8 \cdot 10\text{H}_2\text{O}$, are formed. A. Recoura observed that the hydrate in aq. soln. loses one-third of its fluorine when it is treated with barium chloride. $2\text{FeF}_3 + 3\text{BaCl}_2 = \text{BaF}_2 + 2\text{BaCl}_2 + \text{Fe}_2\text{F}_4\text{Cl}_2$; that the trihydrate, $\text{FeF}_3 \cdot 3\text{H}_2\text{O}$, loses one-third of its fluorine as HF when it is heated; and that when the hydrate is boiled with alcohol two mols. of hydrogen fluoride are evolved quickly and the remainder of the fluorine very slowly. This is all taken to mean that the salt in aq. soln. is in the form of a complex $\text{Fe}_2\text{F}_4(\text{OH})_2(\text{HF})_2 \cdot 4\text{H}_2\text{O}$, which, at 95° is said to form the oxyfluoride $\text{Fe}_2\text{F}_4\text{O}$; but R. Weinland and co-workers represent it by the formula $[\text{Fe}_2\text{F}_2]\text{F}_4$, where the F_4 can be readily replaced by the radicle SiF_6 . The mol. wt. of the salt in aq. soln. with 5.131, 2.879, and 1.439 per cent. FeF_3 was found by A. W. Speransky to be respectively 130.1, 122.2, and 110.5; in soln. with 1.93, and 0.95 per cent. FeF_3 , 118.2 and 112.7 respectively; and E. Deussen and H. Kessler, in soln. with 0.99 per cent. FeF_3 , 161 to 165. R. Weinland and co-workers favoured the formula for the *hemienneahydrate*, $\text{FeF}_3 \cdot 4.5\text{H}_2\text{O}$, obtained by J. J. Berzelius, G. Gallo, and A. Scheurer-Kestner by evaporating the aq. soln. and drying the product over calcium chloride. When this hydrate is heated to 100° , A. Scheurer-Kestner, E. Deussen, A. Recoura, and R. Peters found that it passed into the *trihydrate*, $\text{FeF}_3 \cdot 3\text{H}_2\text{O}$.

C. Poulenc said that the crystals of the anhydrous salt are greenish, transparent, probably triclinic, and pseudorhombohedral; A. de Schulten, that they are pale green, and rhombohedral with an inclination to twinning; H. St. C. Deville, that they are isomorphous with those of aluminium fluoride; and O. Ruff and E. Ascher, that they are isomorphous with those of aluminium fluoride; and O. Ruff and E. Ascher, that they are hexagonal like cobaltic fluoride, and that the X-radiograms show a lattice with $a=7.78 \text{ \AA}$, $c=3.73 \text{ \AA}$, and $a:c=1:0.479$. There are 4 mols. per unit cell. F. Ebert gave for the rhombohedral lattice $a=3.756 \text{ \AA}$, and $\alpha=88^\circ 14.5'$, and for the hexagonal lattice, $a=5.201 \text{ \AA}$, and $c=6.660 \text{ \AA}$, and $a:c=1:1.28$. The vol. of the rhombohedral lattice is 52.06 \AA^3 , and there is one mol. per cell. The calculated sp. gr. is 3.56; and the observed value 3.52. W. Nowacki, and N. Wooster made observations on the subject. J. A. A. Ketelaar found that the crystals are isomorphous with the trifluorides of cobalt, aluminium, rhodium, and palladium. A. Scheurer-Kestner said that the crystals of the hemienneahydrate are colourless; G. Gallo, greenish; J. J. Berzelius, pale flesh-red; and R. Weinland and co-workers, pale rose-red. C. Poulenc gave 3.87 for the sp. gr. of the salt; O. Ruff and E. Ascher, 3.52, when the value calculated from the lattice constants is 3.81. A. Speransky found the lowering of the f.p. of aq. soln. with 5.131, 2.879, and 1.439 per cent. of FeF_3 to be respectively 0.745° , 0.445° , and 0.245° . Observations were also made by R. Peters, and H. Kessler. K. Jellinek and A. Rudat found that the salt is solid at 550° , and C. Poulenc, that it volatilizes above 1000° without melting. K. Jellinek and A. Rudat gave the vap. press., p , of the fluorine at 623° K , 723° K , and 823° K . $\log p = -49.05$, -41.91 , and -35.59 respectively. According to A. Scheurer-Kestner, if the trihydrate be heated above 100° , dehydration is accompanied by decomposition; E. Deussen added that even at 100° , a small proportion is decomposed; and G. Gallo observed that when the salt is warmed at 150° to 200° , it is completely converted into ferric oxide and

hydrogen fluoride. K. Jellinek and co-workers calculated for the heat of formation of ferric fluoride (Fe_2F_6) = 233.25 Cals. at 800° K. The thermal value of the reaction $\text{FeF}_2 + \frac{1}{2}\text{F}_2 = \text{FeF}_3$ is very nearly half the heat of formation of FeF_2 , indicating that the three fluorine atoms are symmetrically placed in the molecule, and have each the thermal value 78.00 Cals. M. Berthelot gave $(2\text{Fe}_2\text{F}_6, \text{Aq.}) = 335.1$ Cals.; E. Petersen gave $2\text{FeCl}_3, \text{Aq.} + 6\text{AgF}, \text{Aq.} = 2\text{FeF}_3, \text{Aq.} + 6\text{AgCl} + 93.8$ Cals., and hence calculated 23.2 to 23.9 Cals. for $\text{Fe}(\text{OH})_3, \text{Aq.} + 3\text{HF}, \text{Aq.}$ O. Ruff and E. Ascher calculated from H. von Wartenberg's data, $(\text{Fe}_2\text{F}_6, \text{Aq.}) = 243.1$ Cals. The heat of solution is $\text{FeF}_3, \text{Aq.} + 6\text{HF}, \text{Aq.} = 1.2$ Cals.

J. J. Berzelius noted that sat. soln. of ferric fluoride are colourless; and A. Byk and H. Jaffe found that for 1 cm. layers of ferric fluoride dissolved in conc. hydrofluoric acid, the absorption spectrum, λ , was respectively 2727, 2700, 2584, and 2448 Å. with soln. $\frac{1}{2}$, $\frac{1}{5}$, and $\frac{1}{50}$ th the initial concentration. According to A. W. Speransky, the sp. electrical conductivity, K , and the conductivity, μ , for soln. with a mol of salt in v litres, are:

v	6	12	24	48	96
K	0.001565	0.000925	0.000563	0.000359	0.000237
v	3.925	5.887	8.883	13.247	19.87
μ	7.6	8.4	9.3	10.4	11.9

The aq. soln. is therefore a poor conductor. R. Weinland and co-workers obtained $\mu=39$ for $v=128$. A. Recoura noted that the hydrolysis of aq. soln. of ferric fluoride is not so great as is the case with soln. of other ferric salts, since the soln. is colourless. This is in agreement with the comparatively small electrical conductivity, and also with A. W. Speransky's observations on the influence of soln. of ferric fluoride on the inversion of cane sugar. R. Peters said that the hydrolysis is perceptible with a dilution $v=96$. R. H. Carter observed that the H^+ -ion conc. of a sat. soln. is $p_{\text{H}}=3.0$, at 25°. If the temp. be augmented, the hydrolysis is greater. J. M. Ordway, for instance, observed that half the iron is precipitated as hydrated oxide when a 0.3 per cent. soln. is boiled. P. Nicolardot also observed that the colloidal hydroxide is produced in hot aq. soln., and this colours the liquid yellow. Unlike soln. of ferric chloride, A. Scheurer-Kestner, and J. M. Ordway observed that soln. of ferric fluoride do not dissolve hydrated ferric oxide. A. Recoura, and R. Weinland and co-workers showed that the degree of ionization of soln. of ferric fluoride is small; and J. Knobloch, L. Szebelledy, and C. Bongiovanni said that ferric ions in aq. soln. of the fluoride do not appear when the soln. is tested with thiocyanate, salicylate, or acetic acid, and antipyrine, and iodine is not liberated from iodides. E. Deussen said that the reactions of Fe^{+++} -ions appear after the soln. has been treated with sulphuric or acetic acid. The smaller conc. of Fe^{+++} -ions in soln. of ferric fluoride than in soln. of other ferric salts was found by R. Peters to be in harmony with the observation that the reduction potential of a soln. of a ferric salt is raised by the addition of F^- -ions owing to the removal of the Fe^{+++} -ions; and in accord with the fact that the conductivity and lowering of the f.p. of mixed soln. of sodium fluoride and ferric chloride are less than the values of these constants calculated by the mixture rule. N. R. Dhar and G. Urbain found that the polarization of iron in soln. of ferric fluoride, agrees with the assumption that complexes are formed in the soln.—*vide supra*. A. Heydweiller studied the dielectric constant of the hydrated salt.

E. Feytis measured the magnetic susceptibility, χ mass units, of the trihydrate and obtained at 13°, $\chi=47.3 \times 10^{-6}$ per gram, or 7899×10^{-6} per mol. P. Weiss calculated from E. Feytis' measurements the magneton number of the trihydrate to be 23. T. Ishiwara calculated the magnetic susceptibility from P. Pascal's datum for a soln. of the salt, $\chi=45.5 \times 10^{-6}$, and for the solid, at 16.5°, he obtained 47.3×10^{-6} . K. Honda and T. Ishiwara observed that the susceptibility decreases with a rise of temp., at first slowly, then rapidly, thus:

$\chi \times 10^6$	99.4°	66.8°	39.8°	12.3°	-3.3°	-27.5°	-66.5°	-105.7°	-162.1°
	42.8	44.8	46.1	47.6	48.7	50.0	52.2	54.0	55.0

According to C. Poulenc, *hydrogen*, at a dull red-heat, reduces ferric fluoride to ferrous fluoride and to the metal. K. Jellinek and A. Rudat found for equilibrium in $2\text{FeF}_3 + \text{H}_2 \rightleftharpoons 2\text{FeF}_2 + 2\text{HF}$, $\log(p^2_{\text{HF}}/p_{\text{H}_2})$ is -3.06 , -1.71 , and -0.52 respectively at 350° , 450° , and 550° ; and for the value of p vol. per cent. of hydrogen fluoride, respectively 2.9, 13.0, and 42.0. The processes of reduction of ferric chloride to ferrous chloride and to iron are endothermal. C. Poulenc found that when ferric fluoride is heated in *air* it readily forms ferric oxide. E. Deussen noted that when the trihydrate is exposed to air, its colour changes from yellow to yellowish-brown, and the proportion of iron is increased; but A. Recoura found that the salt is not changed in dried air. As indicated above, A. Scheurer-Kestner observed that the hydrated salt cannot be heated above 100° without decomposition, and C. Poulenc found that when the salt is heated in *water vapour*, ferric oxide is formed. C. Poulenc, and A. Byk and H. Jaffe noted that the anhydrous salt is sparingly soluble in hot or cold water, and the process of dissolution is slow. A. Recoura said that a cold sat. soln. contains 8 per cent. of FeF_3 ; and R. H. Carter found 0.091 grm. FeF_3 per 100 c.c. of a sat. soln. at 25° . J. J. Berzelius, and A. Scheurer-Kestner also observed that the hydrated salt dissolves in water; and A. Loesche said that one part of the trihydrate dissolves in 80 parts of water. The hydrolysis of the aq. soln. has been discussed above. Well-defined basic salts—**ferric oxyfluorides**—have not been prepared. J. J. Berzelius, and A. Scheurer-Kestner reported that on adding ammonia to the aq. soln. of ferric fluoride, a reddish-brown liquid is not formed as in the case of ferric chloride, but a yellow precipitate of a basic fluoride is formed to which J. J. Berzelius assigned the formula $3\text{Fe}_2\text{O}_3 \cdot 2\text{FeF}_3 \cdot 4\text{H}_2\text{O}$, or $\text{Fe}_8\text{F}_6\text{O}_9 \cdot 4\text{H}_2\text{O}$; A. Scheurer-Kestner, $\text{Fe}_2\text{O}(\text{OH})_3\text{F}$; and P. Nicolardot, $\text{Fe}_2\text{O}_3 \cdot \text{HF} \cdot \text{H}_2\text{O}$. A. Loesche added that the precipitate obtained by treating the aq. soln. with ammonia has no constant composition. Other oxyfluorides have been mentioned without a demonstration that they are chemical individuals. Thus, E. Deussen reported one to be formed by the action of hydrofluoric acid on hammer-scale; A. Recoura, $\text{Fe}_2\text{F}_4\text{O}$, as described above; and C. Poulenc, the formation of a basic salt by hydrolysis.

O. Ruff and E. Ascher observed that *bromine* and *iodine* have no perceptible action on ferric fluoride. C. Poulenc obtained the salt in crystals by heating it in *hydrogen fluoride* at 1000° ; and K. Fredenhagen said that the salt is not perceptibly soluble in liquid hydrogen fluoride. O. Ruff and E. Ascher added that the evaporation of a soln. of the salt in 40 per cent. *hydrofluoric acid* yields a hydrate which is readily hydrolyzed by water. A. Byk and H. Jaffe observed that although ferric fluoride is sparingly soluble in water, it readily dissolves in hydrofluoric acid. K. Fredenhagen and G. Cadenbach studied the subject. C. Poulenc showed that when the salt is heated in a current of *hydrogen chloride*, ferric chloride is formed, and at ordinary temp. the reaction is reversed: $\text{FeF}_3 + 3\text{HCl} \rightleftharpoons \text{FeCl}_3 + 3\text{HF}$. Boiling or cold *hydrochloric acid* has very little action on ferric fluoride; and E. Petersen said that the action of dil. hydrochloric acid on an aq. soln. of ferric fluoride is endothermal. J. Knobloch, C. Bongiovanni, and L. Szebelledy observed that a soln. of ferric fluoride, unlike soln. of ferric salts in general, does not liberate iodine from a soln. of *potassium iodide*. O. Ruff and E. Ascher found that there is no perceptible reaction between ferric fluoride and *sulphur*, although when the product is treated with dil. hydrochloric acid, traces of hydrogen sulphide appear. C. Poulenc observed that at a red-heat *hydrogen sulphide* forms hydrogen fluoride and ferrous sulphide. O. Ruff and E. Ascher found that *sulphur dioxide* slowly reduces ferric to ferrous fluoride. According to C. Poulenc, ferric fluoride is attacked with difficulty, even by boiling *sulphuric acid*. O. Ruff and E. Ascher observed that ferric fluoride is to some extent reduced when it is heated in *ammonia*, forming ferrous and ammonium fluorides. C. Poulenc observed that ferric fluoride is only slightly attacked, even by boiling *nitric acid*. O. Ruff and E. Ascher observed no perceptible reaction when ferric fluoride is heated with red *phosphorus*, or with *arsenic*; nor is there any reaction with *carbon*. C. Poulenc said that ferric

fluoride is insoluble in *alcohol*, and *ether*; and O. Ruff and E. Ascher, that it is insoluble in ether and *benzene*. A. Scheurer-Kestner found that the hydrated fluoride is also insoluble in alcohol. O. Ruff and E. Ascher found that the fluoride is feebly attacked by boiling, 12 per cent. *acetic acid*. R. Weinland and W. Hübner studied the complexes formed with *oxalic acid*. E. Böhm showed that when heated with a soln. of *potassium acetate*, ferric fluoride is decomposed. According to J. Knobloch, L. Szebelledy, and C. Bongiovanni, as indicated above, a soln. of ferric fluoride, unlike soln. of ferric salts in general, does not give colorations with *potassium thiocyanate*, *acetic acid* and *antipyrine*, or *salicylic acid*. F. Calzolari observed that ferric fluoride probably forms a complex salt with *antipyrine*. R. Weinland and co-workers obtained complex salts with *guanidine*, $\text{H}_2(\text{CN}_3\text{H}_5)_2[\text{FeF}_5(\text{H}_2\text{O})]$; with *ethylenediamine*, $\text{H}_2\text{en}[\text{FeF}_5(\text{H}_2\text{O})]$; and with *pyridine*, $\text{H}_2(\text{C}_5\text{H}_5\text{N})_2[\text{FeF}_5(\text{H}_2\text{O})] \cdot 2\text{H}_2\text{O}$, and $\text{H}(\text{C}_5\text{H}_5\text{N})[\text{FeF}_4] \cdot \text{H}_2\text{O}$. J. Nicklès noted that ferric fluoride forms complexes with *quinine*, and *brucine*. A. Recoura also obtained a complex with *silicon tetrafluoride*, $\text{FeF}_3 \cdot \text{SiF}_4$. H. St. C. Deville and H. Caron noted that when ferric fluoride is heated with *boric oxide*, in the absence of air, ferric oxide and boron fluoride are formed. O. Ruff and E. Ascher observed that when ferric fluoride is heated with crystalline *silicon*, the attack is attended by a glow; *sodium* also reacts with incandescence; no perceptible reaction occurs with *copper*; *magnesium* reacts explosively; *zinc* reacts with the evolution of much heat; and similarly with *aluminium*; whilst *iron* reacts strongly when heated with ferric fluoride, forming ferrous fluoride. A boiling, 33 per cent. soln. of *sodium hydroxide* acquires a colour, and brown hydrated ferric oxide is deposited. C. Poulenc noted that molten *sodium carbonate* converts the fluoride into ferric oxide and sodium fluoride. A. Recoura—*vide supra*—studied the action of *barium chloride* on the aq. soln. and it resulted in the formation of **ferric fluochloride**, $\text{Fe}_2\text{F}_4\text{Cl}_6$.

The complex salts were discussed by P. Barteczko, and R. Weinland and co-workers, and, according to H. von Helmolt, they form isomorphous series with the complex aluminium and chromium fluorides. R. Weinland and co-workers prepared **ammonium tetrafluoferrate**, $\text{NH}_4[\text{FeF}_4]$; crystals of **ammonium hexafluoferrate**, $(\text{NH}_4)_3[\text{FeF}_6]$, were prepared by R. Wagner, and the salt was studied by P. Weiss and E. Feytis, L. Pauling, H. von Helmolt, and J. C. G. de Marignac. J. Nicklès found that the mixed soln. of ferric and ammonium fluorides, or that obtained by mixing ammonium fluoride with ferric chloride, furnishes **ammonium ferric fluoride**, or **ammonium pentafluoferrate**, $(\text{NH}_4)_2\text{FeF}_5$, but J. C. G. de Marignac showed that the salt has the composition $(\text{NH}_4)_3\text{FeF}_6$. The crystals are small, colourless, regular octahedra, with no birefringence. L. Pauling found that the cubic crystals of **ammonium ferric hexafluoride**, $(\text{NH}_4)_3\text{FeF}_6$, have a face-centred lattice, containing 4 mols., with $a=9.10 \text{ \AA}$. H. Seifert studied the subject. J. Nicklès found that the crystals do not lose weight in air at 100° , but when roasted in air, ferric oxide is formed. The salt is less soluble in water than the corresponding potassium salt, and the boiling aq. soln. is hydrolyzed, and yellow flecks of an hydroxide or basic salt separate. Lead acetate gives a precipitate which is yellow when hot; lead nitrate, a precipitate which is not yellow. Bismuth nitrate gives a white precipitate from the hot soln.; ammonia precipitates hydrated ferric oxide; potassium ferrocyanide, and gallic acid give blue precipitates; and potassium thiocyanate, a red precipitate. H. Remy and H. Busch prepared a number of substituted ammonium salts—e.g., the **methylammonium ferric fluorides**: $\{\text{NH}_3(\text{CH}_3)\}\text{FeF}_4$; $\{\text{NH}_3(\text{CH}_3)_2\}\text{FeF}_5$; and $\{\text{NH}_3(\text{CH}_3)_3\}\text{FeF}_6$; the **dimethylammonium ferric fluorides**: $\{\text{NH}_2(\text{CH}_3)_2\}\text{FeF}_4 \cdot \text{H}_2\text{O}$; $\{\text{NH}_2(\text{CH}_3)_2\}_2\text{FeF}_5 \cdot 2\text{H}_2\text{O}$; $\{\text{NH}_2(\text{CH}_3)_2\}_2\text{FeF}_4 \cdot \text{HF}_2$; and $\{\text{NH}_2(\text{CH}_3)_2\}_3\text{FeF}_6 \cdot 2\text{HF}$; the **trimethylammonium ferric fluoride**: $\{\text{NH}(\text{CH}_3)_3\}_2\text{FeF}_5 \cdot 2\text{HF}$; the **tetramethylammonium ferric fluoride**: $\{\text{N}(\text{CH}_3)_4\}\text{FeF}_4 \cdot \text{H}_2\text{O}$; **ethylammonium ferric fluorides**: $\{\text{NH}_3(\text{C}_2\text{H}_5)\}_2\text{FeF}_5 \cdot \text{HF}$; and $\{\text{NH}_3(\text{C}_2\text{H}_5)\}_3\text{FeF}_6 \cdot 2\text{HF}$; **propylammonium ferric fluorides**: $\{\text{NH}_3(\text{C}_3\text{H}_7)\}_2\text{FeF}_5 \cdot \text{HF}$; and $\{\text{NH}_3(\text{C}_3\text{H}_7)\}_3\text{FeF}_6 \cdot 2\text{HF}$; **butyl-**

ammonium ferric fluorides : $\{\text{NH}_3(\text{C}_4\text{H}_9)\}_3\text{FeF}_4 \cdot 2\text{H}_2\text{O}$; $\{\text{NH}_3(\text{C}_4\text{H}_9)\}_2 \cdot \text{FeF}_5 \cdot \text{HF}$; and $\{\text{NH}_3(\text{C}_4\text{H}_9)\}_3\text{FeF}_6 \cdot 2\text{HF}$.

E. Wilke-Dörfurt and H. G. Mureck obtained *ferric hexantipyridinoboro-fluoride*, $[\text{Fe}(\text{COC}_{10}\text{H}_{12}\text{N}_2)_6](\text{BF}_4)_3$. R. F. Weinland and co-workers prepared *pyridinium tetrafluoroferrate*, $[(\text{C}_5\text{H}_5\text{N})\text{H}][\text{FeF}_4] \cdot \text{H}_2\text{O}$; *pyridinium pentafluoroferrate*, $[(\text{C}_5\text{H}_5\text{N})_2\text{H}_2][\text{FeF}_5] \cdot \text{H}_2\text{O}$; *ethylenediaminoammonium pentafluoroferrate* $[\text{en}_2\text{H}_2][\text{FeF}_5] \cdot \text{H}_2\text{O}$; and *guanidinium pentafluoroferrate*, $[(\text{CH}_3\text{N}_3)_2\text{H}_2][\text{FeF}_5] \cdot \text{H}_2\text{O}$. H. Busch obtained *methylammonium*, *dimethylammonium*, *trimethylammonium*, *tetramethylammonium*, *ethylammonium*, *propylammonium*, and *butylammonium fluo-ferrates*.

J. J. Berzelius, J. Nicklès, and P. Guyot prepared **potassium hexafluoroferrate**, or *potassium ferric hexafluoride*, which they represented as $4\text{KF} \cdot 2\text{FeF}_3 \cdot \text{H}_2\text{O}$. A. Greeff, and P. Guyot studied this compound. R. Weinland and co-workers prepared **potassium tetrafluoroferrate**, $\text{K}[\text{FeF}_4]$; and J. J. Berzelius, **potassium pentafluoroferrate**, $\text{K}_2[\text{FeF}_5]$. J. Nicklès obtained crystals of the hemihydrate, and O. T. Christensen, crystals of the monohydrate. R. Wagner showed that the composition is best represented by $\text{K}_3[\text{FeF}_6]$. The potassium salt resembles the ammonium salt. F. Röder prepared **sodium pentafluoroferrate**, $\text{Na}_2[\text{FeF}_5]$, and J. Nicklès, the hemihydrate. J. J. Berzelius, and J. Nicklès, prepared **sodium ferric fluoride**, or **sodium hexafluoroferrate**, in an analogous manner. The salt is also obtained as a white, crystalline precipitate by adding ferric chloride or fluoride to a neutral soln. of sodium fluoride. J. Nicklès represented the composition of the salt by the formula $4\text{NaF} \cdot 2\text{FeF}_3 \cdot \text{H}_2\text{O}$, but R. Wagner showed that the salt has the composition Na_3FeF_6 ; and A. Greeff added that it does not give a red coloration with potassium thiocyanate, which shows that the iron atom is part of the anion. R. Peters obtained the *hemihydrate*, $2\text{Na}_3\text{FeF}_6 \cdot \text{H}_2\text{O}$. According to A. V. Baskoff, sodium and ferric fluorides form a eutectic mixture which melts at 892° , and contains 65 molar per cent. of sodium fluoride. R. Wilke observed that sodium salts precipitate from soln. of ferric fluoride the salt Na_3FeF_6 , or *iron cryolite*. R. Weinland and co-workers prepared blue **copper hexafluoroferrate**, $(\text{FeF}_6)_2[\text{Cu}(\text{H}_2\text{O})_6]$; and colourless **silver pentafluoroferrate**, or silver fluoferrite, $\text{Ag}_2[\text{FeF}_5(\text{H}_2\text{O})] \cdot 2\text{H}_2\text{O}$. A. Recoura reported **barium hexafluoroferrate**, $\text{Ba}_3(\text{FeF}_6)_2$, to be formed as a precipitate when a soln. of barium chloride is added to one of ferric fluoride. R. F. Weinland and O. Köppen prepared **zinc pentafluoroferrate**, $\text{ZnFeF}_5 \cdot 7\text{H}_2\text{O}$, by mixing soln. of the component salts. The solid is colourless in thin layers, red in thick layers. It is sparingly soluble in dil. hydrofluoric acid, and does not effloresce over conc. sulphuric acid. The corresponding **cadmium pentafluoroferrate**, $\text{CdFeF}_5 \cdot 7\text{H}_2\text{O}$, or $[\text{FeF}_5(\text{H}_2\text{O})][\text{Cd}(\text{H}_2\text{O})_6]$, was also prepared. F. Ephraim and P. Barteczko prepared **thallous ennefluoroferrate**, $3\text{TlF} \cdot 2\text{FeF}_3$, or $\text{Tl}_3(\text{Fe}_2\text{F}_9)$, in pink crystals, by evaporating a soln. of thallous fluoride and an excess of ferric fluoride. R. Weinland and co-workers also obtained the rose-red salt $\text{Tl}_2[\text{FeF}_5(\text{H}_2\text{O})] \cdot 2\text{H}_2\text{O}$. R. F. Weinland and O. Köppen obtained **ferrous pentafluoroferrate**, $\text{Fe}''\text{Fe}'''\text{F}_5 \cdot 7\text{H}_2\text{O}$, or $\text{FeF}_3 \cdot \text{FeF}_2 \cdot 7\text{H}_2\text{O}$, or $[\text{Fe}'''\text{F}_5(\text{H}_2\text{O})][\text{Fe}''(\text{H}_2\text{O})_6]$, or $\text{Fe}(\text{FeF}_5) \cdot 7\text{H}_2\text{O}$, in yellow crystals by the action of ferrous carbonate on a hydrofluoric acid soln. of hydrated ferric oxide. They also prepared **cobalt pentafluoroferrate**, $\text{Co}(\text{FeF}_5) \cdot 7\text{H}_2\text{O}$; and **nickel pentafluoroferrate**, $\text{Ni}(\text{FeF}_5) \cdot 7\text{H}_2\text{O}$, in a similar manner. *Vide supra*, for E. Deussen's $\text{FeF}_2 \cdot 2\text{FeF}_3 \cdot 10\text{H}_2\text{O}$.

§ 36. The Iron Chlorides—Ferrous Chloride

Iron forms two chlorides—**ferrous chloride**, FeCl_2 , and **ferric chloride**, FeCl_3 . E. Darmstädter¹ suggested that the vague and indefinite remarks on the sublimation of vitriol, by Geber, in his *Summa perfectionis*, might refer to sublimed ferric chloride prepared by heating ferric oxide with sal ammoniac. In 1648,

J. R. Glauber prepared iron chloride by dissolving iron in hydrochloric acid, and evaporating the soln. He thus obtained an impure chloride as a blood-red mass of ferric chloride. The crystals when placed in a soln. of potassium silicate, furnished a branched structure which was later called *Glauber's iron tree*. R. Boyle, in 1690, obtained crystals from a soln. of iron in hydrochloric acid, and found that they were soluble in spirits of wine. The alcoholic soln. of the iron chloride afterwards acquired some celebrity as a medicine under various names—e.g., *Bestuscheff's tinctura tonico-nervina*, named after the Russian General Bestuscheff; and *Lamotte's gold drops*, named after the French officer, M. Lamotte—and its mode of preparation was kept secret until about the end of the eighteenth century. M. Neumann, C. W. Juch, J. B. van Mons, G. Kerner, F. W. Krüger, and M. H. Klaproth described its preparation by heating a mixture of iron pyrites and mercuric chloride, isolating the iron salt from the products of the reaction, and dissolving the salt in rectified wine. The anhydrous sublimed chlorides were discussed by F. A. C. Gren in 1795; and H. Davy, and J. Davy showed the relation between the composition and nature of the two chlorides.

The presence of ferrous chloride has been observed in native iron—e.g., that of Ovivak, Greenland—and in meteorites—e.g., that of Claiborne, Alabama, etc.—by C. T. Jackson,² J. L. Smith, etc. The chloride is often accompanied by some nickel chloride, NiCl_2 . The ferrous chloride is coloured green to brown. The ferrous chloride occurring under these conditions was called **lawrencite**, by A. Daubrée—after J. Lawrence Smith. In some cases, ferric chloride formed by the oxidation of lawrencite exudes from the surface of meteoric iron in drops, called by A. Daubrée, *stigmatite*—from *στάγμα*, drops. The existence of ferrous chloride in the sublimates at Vesuvius was demonstrated by T. Monticelli and N. Covelli. J. T. Conroy observed its formation in the superheater of the decomposer of a chlorine plant.

The formation and preparation of ferrous chloride.—Anhydrous ferrous chloride can be obtained by the action of chlorine on heated iron (*q.v.*), as recommended by L. J. Thénard,³ but it is difficult to prevent the chlorination going too far and furnishing ferric chloride (*q.v.*). Ferrous chloride is better prepared by passing hydrogen chloride over iron at a red-heat. K. A. Hofmann and co-workers said that the reaction is perceptible at 285° , and F. Schmitz recommended a temp. of 1000° . The process is described in several books of laboratory preparations—e.g., H. and W. Biltz, L. Vanino, etc. M. Berthelot said that the reaction is possible because the heat of formation of ferrous chloride is greater than that of hydrogen chloride, but this is not all the story—1, 12, 3. The equilibrium conditions, $\text{Fe} + 2\text{HCl} \rightleftharpoons \text{FeCl}_2 + \text{H}_2$, were discussed by F. Isambert, and A. B. Bagdasarian—*vide infra*. L. F. Nilson and O. Pettersson used a platinum tube; F. Girardet, a porcelain tube; and W. Biltz and E. Birk, a vitreous quartz tube. The ferrous chloride appears as a molten mass, which crystallizes on cooling, and at a high enough temp., the product may occur in sublimed plates. V. Meyer purified ferrous chloride by sublimation in an atm. of hydrogen chloride. H. Wolfram said that a part of the iron escapes attack, and G. J. Fowler recommended removing it by means of a magnet. H. Wolfram said that in the sublimed product iron may be present owing to the temp. being high enough to dissociate some of the chloride. E. Kohn-Abrest added that the product may contain some ferric chloride. The process was also described by H. and W. Biltz, A. Geuther and E. Forsberg, W. Hampe, E. Diepschlag, F. Huttner, A. S. Miller, and A. E. Nordenskjöld. J. Meyer and R. Backa obtained ferrous chloride accompanied by vanadium dichloride by the action of hydrogen chloride on ferrovanadium at 300° to 400° . H. Moissan obtained ferrous chloride by the action of hydrogen chloride on iron carbide at 600° ; the Badische Anilin- und Sodafabrik, by its action on chromite; and F. Bullheimer, and A. C. Knowles, on ferruginous clays.

J. S. F. Pagenstecher prepared ferrous chloride by heating iron filings with an excess of ammonium chloride. A. W. F. Rogstadius added that a trace of ferric

chloride is also formed. The process was examined by J. Fischler, H. Hampel, H. Hampel and R. Steinau, K. A. Hofmann and co-workers, A. S. Miller, and J. Thomsen. Ferrous chloride is formed when various chloride vapours act on iron at an elevated temp.—*e.g.*, sodium chloride: $\text{Fe} + 2\text{NaCl} \rightleftharpoons \text{FeCl}_2 + 2\text{Na}$ (L. Hackspill and R. Grandadam); aluminium chloride $3\text{Fe} + 2\text{AlCl}_3 \rightleftharpoons 3\text{FeCl}_2 + 2\text{Al}$ (H. St. C. Deville); carbon tetrachloride (E. Berger); carbonyl chloride (W. Heap and E. Newbery); silicon tetrachloride (E. Vigouroux, and C. Pape); phosphorus trichloride (A. Granger); phosphorus pentachloride: $\text{PCl}_5 + \text{Fe} \rightleftharpoons \text{FeCl}_2 + \text{PCl}_3$ (E. Baudrimont, and H. Goldschmidt); phosphoryl chloride (B. Reinitzer and H. Goldschmidt); sulphur monochloride (P. Nicolardot); and thionyl chloride (K. Ott, and H. B. North and A. M. Hageman).

M. Berthelot discussed the formation of ferrous chloride by the action of chlorine on ferrous oxide; H. St. C. Deville, by the action of hydrogen chloride on ferrous oxide: $4\text{FeO} + 2\text{HCl} = \text{Fe}_3\text{O}_4 + \text{FeCl}_2 + 2\text{H}$; and G. Rauter, by the action of silicon tetrachloride in a sealed tube at 370° to 380° . H. St. C. Deville also obtained ferrous chloride by the action of hydrogen chloride on strongly-heated ferric oxide; J. B. Moyer, by the action of hydrogen chloride on ferric oxide at 200° when much volatile ferric chloride is formed—F. A. Gooch and F. S. Havens said 90 to 95 per cent.

F. Wöhler obtained ferrous chloride by heating ferric chloride in hydrogen, but, added E. Péligot, at not too high a temp. or the ferrous chloride which is formed will be reduced to the metal. The process was discussed by A. S. Miller, and H. Wolfram. A. B. Bagdasarian recommended heating a mixture of ferric chloride and powdered iron in an atm. of hydrogen and hydrogen chloride (1 : 1). P. Fireman heated a mixture of ferric chloride and ammonium chloride in a sealed tube at 400° to 420° . L. E. Jonas, and A. Benrath exposed an ethereal soln. of ferric chloride to light and obtained ferrous chloride as a white scaly powder; A. W. Ralston and J. A. Wilkinson obtained it as a white precipitate from a soln. of ferric chloride in liquid hydrogen sulphide at ordinary temp.; and V. Thomas, by the action of nitric oxide on ferric chloride: $\text{FeCl}_3 + \text{NO} = \text{NOCl} + \text{FeCl}_2$. V. Thomas also observed that the complex FeCl_2NO yields ferrous chloride when heated in a neutral atm. Ferric chloride is reduced to ferrous chloride by numerous other reagents. H. E. Williams passed an electric current of low current density through a dil. ethereal soln. of ferric chloride, and observed the formation of ferrous chloride at the cathode.

Numerous compounds of iron yield ferrous chloride when treated with chlorine, hydrogen chloride or chlorides. E. Kothny, and C. F. Prutton observed its formation in the chloridizing roast of pyrites; W. S. Millar, by the action of chlorine on mixtures of ferric oxide and sulphur or sulphur compounds. A. P. Brown obtained it by the action of hydrogen chloride on pyrites; and S. I. Levy and G. W. Gray, by the action of ferric chloride on pyrites at 500° to 1000° , thus $2\text{FeCl}_3 + \text{FeS}_2 = 3\text{FeCl}_2 + 2\text{S}$, or the action of chlorine at 700° to 800° : $\text{FeS}_2 + \text{Cl}_2 = \text{FeCl}_2 + 2\text{S} + 46.5 \text{ Cals.}$ —at this temp. many foreign chlorides are volatilized; the reaction sets in at about 250° . Ferrous chloride is formed by the action of the vapour of chloroform on ferrous sulphate (A. Conduché); the reaction begins at 300° ; by the action of iron carbonyl on a soln. of mercuric chloride in acetone (H. Hock and H. Stuhlmann); by the photochemical decomposition of iron chlorocarbonyl, $\text{Fe}(\text{CO})_4\text{Cl}_2$ (W. Hieber and G. Bader); and by the action of titanium tetrachloride on ferrous carbonate or titanate (C. Friedel and J. Guérin).

F. A. C. Gren, J. Davy, E. L. Schubarth, and T. Graham obtained the anhydrous salt by heating hydrated ferrous chloride. J. J. Berzelius heated the hydrate in a retort, and after the evolution of water, hydrogen chloride, and ferric chloride had ceased, raised the temp. to a white-heat to volatilize the ferrous chloride. N. Costachescu and G. Spacu recommended dehydrating the hydrate in an atm. of carbon dioxide; W. Biltz and G. F. Hüttig, in an atm. of hydrogen chloride at 120° to 130° ; and A. Geuther and E. Forsberg, with ammonium chloride—in the latter

case, a soln. of hydrated ferrous chloride was mixed with ammonium chloride, dried, and heated in the absence of air.

The hydrates of ferrous chloride.—A soln. of ferrous chloride is obtained by dissolving iron, or ferrous oxide, hydroxide or carbonate in hydrochloric acid in the absence of air. H. Hess said that if conc. acid be used with iron, crystals separate from the soln. and these dissolve in water with decrepitation and the evolution of an inflammable gas—presumably derived from the carbide in the iron. The ferrous compounds are not easily obtained quite free from oxidation products, so that the soln. may be contaminated with ferric chloride. H. Meyer accordingly recommended filtering the soln. through a column of iron turnings in an atm. of carbon dioxide. J. H. Long discussed the preparation of a soln. free from acid; and R. Phillips recommended adding barium chloride to a soln. of ferrous sulphate in a neutral atm. The preparation of soln. of ferrous chloride from various by-products was described by F. J. R. Carulla, C. Mené, and

FIG. 560.—The Solubility of Ferrous Chloride in Water.

R. H. Muench. The evaporation of the aq. soln. furnishes various hydrates. According to A. Reimann, the aq. soln. sat. at room temp. contains 38.1 per cent. FeCl_2 ; J. T. Dunn found 37.53 per cent. at 15.5° ; H. E. Boeke, 39.8, 41.6, and 42.2 per cent. respectively at 22.8° , 38.0° , and 43.2° ; and Y. Osaka and T. Yaginuma, 39.61 per cent. at 25° . Observations were made by F. Jahn, "Abl.," and C. F. Wenzel. A. Étard's data for the percentage solubility, S , are :

	10°	20°	30°	50°	60°	80°	100°	120°
S	39.2	40.7	42.2	45.2	47.0	50.0	51.4	51.8
	$\text{FeCl}_2 \cdot 4\text{H}_2\text{O}$					$\text{FeCl}_2 \cdot 2\text{H}_2\text{O}$		

The following is a selection from F. Schimmel's data, plotted in Fig. 560 :

	-9°	-36.5°	-20°	-3.0°	12.3°	25.0°	76.5°	86.0°	117.5°
S	14.5	30.4	31.0	32.6	37.6	39.2	47.4	47.7	50.4
	Ice		$\text{FeCl}_2 \cdot 6\text{H}_2\text{O}$		$\text{FeCl}_2 \cdot 4\text{H}_2\text{O}$		$\text{FeCl}_2 \cdot 2\text{H}_2\text{O}$		

so that the eutectic temp. with the hexahydrate is -36.5° , with soln. containing 30.4 per cent. of FeCl_2 . The transition temp. for the hexahydrate and tetrahydrate is 12.3° ; and for the tetrahydrate and dihydrate, 76.5° . H. E. Boeke gave 72.2° to 72.6° ; and R. Kremann and F. Noss, 65.2° . H. E. Boeke found that there is an increase in vol. at the tetrahydrate and dihydrate transition temp., and the transition temp. is lowered in the presence of sodium or magnesium chloride. J. Eggert and J. Reitstötter discussed the relation between the transition temp. and the water of crystallization and number of atoms in the molecule.

J. Thomsen suggested that there is probably a **hexahydrate**, $\text{FeCl}_2 \cdot 6\text{H}_2\text{O}$, and P. Pfeiffer represented the formula $[\text{Fe}(\text{H}_2\text{O})_6]\text{Cl}_2$ —*vide infra*. This hydrate was isolated by H. Lesœur in the form of pale green, unstable crystals, by cooling a neutral, sat. aq. soln. He thought that since other observers had always obtained a tetrahydrate, his hexahydrate must be produced in neutral soln. under conditions where in the acidic soln. the tetrahydrate is formed. P. Sabatier, indeed, denied the existence of the hexahydrate. G. Agde and F. Schimmel, however, showed that the discrepancy is not due to the use of a neutral or acidified soln., but is rather an effect of temp. The transition point, 12.3° , is very near the ordinary temp. of a room, in some cases one hydrate is formed, in other cases, the other hydrate. All depends on the temp. of the soln. H. Lesœur recommended cooling a neutral soln. of ferrous chloride, sat. at 10° , down to -15° . There is a tendency to under-cooling. G. Agde and F. Schimmel observed that when hydrogen

chloride is passed into a cold sat. soln. of the gas, the absorption of the hydrogen chloride raises the temp. of the soln. above the transition temp., thus giving rise to the idea that the hexahydrate is not formed in acidic soln. The crystals obtained by R. Boyle, J. J. Berzelius, E. L. Schubarth, L. J. Thénard, P. A. von Bonsdorff, T. Graham, and A. Reimann by evaporation and cooling an aq. soln. of the salt, were the **tetrahydrate**, $\text{FeCl}_2 \cdot 4\text{H}_2\text{O}$, which A. Werner represented by the co-ordination formula $[\text{Fe}(\text{H}_2\text{O})_4]\text{Cl}_2$. The subject was discussed by R. Reinicke. H. Lescœur obtained it by passing hydrogen chloride into a sat. soln. of ferric chloride; the necessary condition is that the temp. of the soln. must exceed 12.3° as pointed out by G. Agde and F. Schimmel, Fig. 560; A. Benrath found that the tetrahydrate is deposited when a soln. of hydrated ferric chloride in methyl alcohol is exposed to sunlight, and H. E. Williams by the electrolysis of an ethereal soln. of hydrated ferric chloride. H. Lescœur obtained the **dihydrate**, $\text{FeCl}_2 \cdot 2\text{H}_2\text{O}$, by dehydrating the tetrahydrate at 70° to 90° . The conditions of existence are shown in F. Schimmel's diagram, Fig. 560. H. E. Boeke found that the dihydrate separates from a sat. soln. at 72.6° , and in the presence of magnesium chloride, at 43.2° . R. Kremann and F. Noss' value, 65.2° , for the transition temp. is low. P. Sabatier said that it is formed when the tetrahydrate is kept for a few months over sulphuric acid in vacuo at 20° . The observations of H. Lescœur, and P. Sabatier on the formation of the dihydrate by passing hydrogen chloride into an aq. soln. of ferrous chloride are explained by the need for allowing for the raising of the temp. of the soln. when the gas is introduced, and the need for keeping the crystallizing soln. above the transition temp., 76.5° . L. E. Jonas found that an ethereal soln. of hydrated ferric chloride deposits the dihydrate; E. Puxeddu, that an ethereal soln. of anhydrous ferric chloride deposits the dihydrate in sunlight; and A. Benrath, that a similar result is obtained with a soln. in absolute ethyl alcohol. F. Reitzenstein obtained the dihydrate by keeping the complex $\text{FeCl}_2 \cdot 3\text{Py} \cdot 2\text{H}_2\text{O}$ over conc. sulphuric acid for some months. H. Chandra found that molten $\text{Fe}_3\text{Cl}_8 \cdot 10\text{H}_2\text{O}$ deposits crystals of the dihydrate. H. Lescœur observed that vap. press. measurements indicate the formation of a *monohydrate*, at a temp. exceeding 120° ; and the observations of K. Honda and T. Ishiwara on the magnetic susceptibility indicate that the monohydrate is formed at 161° , and that at 220° , this passes into the anhydrous chloride.

The physical properties of ferrous chloride.—The anhydrous chloride was described by J. Davy, H. Davy, J. S. F. Pagenstecher, A. E. Nordenskjöld, V. Meyer, W. Hampe, and F. Girardet as forming white plates resembling talc, or anthracene; and, according to C. F. Rammesberg, they have a mother-of-pearl lustre. L. F. Nilsson and O. Pettersson said that the molten salt solidifies to a radiating crystalline mass the colour of siderite. H. de Senarmont said that the tabular **crystals** are six-sided, optically uniaxial, and negative; A. E. Nordenskjöld said that the plates belong to the hexagonal system. G. Bruni and A. Ferrari added that the crystals are rhombohedral with a space-lattice like the chlorides of magnesium, cadmium, and manganese; and axial ratio is $a : c = 1 : 2.45$; and $a = 7.155 \text{ \AA}$, and $c = 17.52 \text{ \AA}$. S. Surawicz discussed the symmetry of the crystals of ferrous chloride and its hydrates; and W. Klemm, the energy of the crystal lattice. H. Lescœur said that the crystals of the hexahydrate are pale green; and L. J. Thénard, J. J. Berzelius, and E. L. Schubarth also said the crystals of the tetrahydrate are pale green; and A. Benrath's crystals from methyl alcohol soln., were bluish-green. P. A. von Bonsdorff added that the light-blue crystals of the tetrahydrate become grass-green on exposure to air, and then acquire a surface film coloured yellowish-brown. According to A. Johnsen, the crystals are colourless when viewed by transmitted light parallel to the (100)-face, and pale bluish-green when viewed parallel to the (010)-face. J. Schabus added that the crystals are rarely transparent, mostly translucent. They are rather brittle, with a conchoidal or splintery fracture; the taste appears at first to be piercing, then sweet and astringent, and then metallic. F. A. Flückiger said that the taste is saline, and not bitter like that of ferric chloride.

According to E. L. Schubarth, P. A. von Bonsdorff, A. Reimann, and J. Schabus, the crystals are rhombic prisms, octahedra, or, if crystallized rapidly, plates. A. Johnsen calculated for the rhombic crystals from J. Schabus' measurements, the axial ratios $a : b : c = 1.1946 : 1 : 1.6354$; B. Gossner calculated from A. Johnsen's measurements, on the assumption that the crystals are monoclinic, $a : b : c = 1.1844 : 1 : 1.6358$, and $\beta = 111^\circ 11'$. O. Lehmann studied the twinning of the monoclinic crystals. A. Johnsen said that the twinning occurs about the (001)-plane; and that the cleavage on the (001)-face is perfect, whilst that on the (111)-face is imperfect. B. Gossner added that the optical character is negative, and that the optic axial angle $2E = 65^\circ$ nearly. L. E. Jonas described the crystals of the dihydrate as green; H. E. Boeke, pale green or colourless; and E. Puxeddu, white. O. Lehmann said that the needle-like crystals are monoclinic, with frequent **twinning**; H. E. Boeke observed that the **birefringence** is strong, the twinning may be cruciform, that the monoclinic crystals have $\beta = 130.5^\circ$, and that they are probably isomorphous with dihydrated manganous chloride. O. Lehmann discussed the solid soln. with ammonium chloride.

V. Meyer found the **vapour density** of anhydrous ferrous chloride in an atm. of hydrogen chloride at a yellow-heat to be 6.38 to 6.67 (air unity). These numbers are between the values required for a molecular weight of 126.8 for FeCl_2 and 253.6 for Fe_2Cl_4 . A. Ladenburg, and J. Dewar and A. Scott also obtained results showing that the vapour corresponds with an equilibrium mixture $\text{Fe}_2\text{Cl}_4 \rightleftharpoons 2\text{FeCl}_2$. According to L. F. Nilson and O. Pettersson, the dissociation is complete between 1300° and 1500° for the vapour density between 1300° and 1400° is 4.34, and between 1400° and 1500° , 4.29 when the theoretical value for FeCl_2 is 4.375. A. Werner and W. Schmujooff found that in a boiling soln. of pyridine the mol. wt. is 110 corresponding with the value 126 calculated for the simple formula FeCl_2 . J. Schröder, however, could not confirm this since he always obtained a raising and not a lowering of the b.p. H. Goldschmidt and K. L. Syngros calculated from the f.p. of aq. soln. having 0.205 to 1.999 grm. FeCl_2 per 100 grms. of water, values for the mol. wt. ranging from 44.3 to 48.2. Analogous results were obtained by W. Biltz, and R. Peters. This is taken to mean that the salt is ionized $\text{FeCl}_2 \rightleftharpoons \text{Fe}^{++} + 2\text{Cl}^-$ in aq. soln. The potential measurements of S. Labendzinsky show that the conc. of the Fe^{++} -ions in $N\text{-FeCl}_2$ at 18° is about 2.5 times as great as in $0.1N\text{-FeCl}_2$; and O. Baudisch and P. Mayer said that the evidence indicates that complexes are formed in aq. soln. such that $2\text{FeCl}_2 \rightleftharpoons \text{Fe}^{++} + \text{FeCl}_4^{--}$. H. Lessheim and co-workers discussed the co-ordination number of iron in $[\text{FeCl}_4]^{--}$, and the electronic configuration of the Fe^{++} -ion.

E. Filhol gave 2.528 for the **specific gravity** of the anhydrous chloride; and J. P. Grabfield, 2.988 at 17.9° . W. Biltz and E. Birk obtained for the salt which had been melted in an atm. of hydrogen chloride, 3.162 at $25^\circ/4^\circ$. A. Ferrari and co-workers calculated from the lattice constants 3.254. A. Balandin obtained 2.985 by calculation from an empirical relation between the heat of formation and the at. vol. E. Filhol gave 1.926 for the sp. gr. of the tetrahydrate; J. Schabus, 1.937; and A. Johnsen, 1.96; and G. Heyne obtained 2.358 for the sp. gr. of the dihydrate. H. Becquerel found the sp. gr. of soln. with 6.6, 13.2, 26.41, and 52.83 grms. of FeCl_2 per 100 c.c. of soln. at about 16° , the respective values 1.0548, 1.1093, 1.2141, and 1.4331. A. Heydweiller obtained for soln. with 0.25, 1.0, 2.0, and 3.0 mols of FeCl_2 per litre at $18^\circ/4^\circ$, the respective values 1.02779, 1.1085, 1.2122, and 1.3130; and W. Biltz and J. Meyer, for soln. with 0.0256, 0.08775, 0.3050, and 0.3994 mol of FeCl_2 per litre, the respective sp. gr. 1.003, 1.012, 1.043, and 1.056. Observations were also made by F. W. J. Clendinnen, G. T. Gerlach, and G. Quinke. J. T. Dunn found that the sp. gr. is almost proportional to the percentage proportion of FeCl_2 in soln. since he obtained for soln. with FeCl_2 -per cent. of the anhydrous salt at 15.5° :

FeCl_2	5.40	10.47	15.24	19.68	23.86	27.75	31.39	34.80	37.33	per cent.
Sp. gr.	1.05	1.10	1.15	1.20	1.25	1.30	1.35	1.40	1.44	

W. Biltz, and W. Biltz and E. Birk found the **molecular volume** of anhydrous ferrous chloride to be 40·10 at 25°, and that the formation of the salt from its elements is attended by a small dilation; and J. J. Saslawsky, and W. Klemm came to the same conclusion. F. Ephraim and co-workers also studied the mol. vol.; H. H. Stephenson, the relation between the mol. vol. and the contraction; F. Teltscher, and R. Reinicke, the relation between the mol. vol. and the structure. S. Surawicz, and A. Balandin discussed the mol. vol. of the tetrahydrate; and C. A. Valson examined the contraction which occurs when ferrous chloride is dissolved in water. J. Schabus gave for the **hardness** of the crystals of the tetrahydrate 2·0 on Mohs' scale.

T. Graham made observations on the **rate of diffusion** of ferrous chloride in aq. soln.; and J. C. Graham found the diffusion coeff. in 2 to 5 per cent. soln., at 14° to 16°, to be 0·583 sq. cm. per day—*i.e.* nearly twice as fast as is the case with ferrous sulphate—and the coeff. is not much affected by variations of concentration between these limits. T. Redwood studied the diffusion of the salt through a membrane, and E. Deiss and G. Schikorr observed that no hydrolysis occurs during the diffusion. The **surface tension** of the soln. was studied by G. Wertheim; the effect of a magnetic field on the ascent of the soln. in capillary tubes, by G. Wertheim, G. Quincke, and O. Liebknecht and A. P. Wills; and Z. H. Skrapu and co-workers, the ascent of soln. of the salt in filter-paper.

H. Goldschmidt and K. L. Syngros found the **lowering of the freezing-point** of aq. soln. with 0·205, 0·928, 1·531, and 1·999 grms. FeCl₂ per 100 grms. of water to be respectively 0·088°, 0·374°, 0·609°, and 0·788°; W. Biltz and J. Meyer found for soln. with 0·0256, 0·08775, 0·3050, and 0·3994 mol of FeCl₂ per litre, the respective values 0·133°, 0·452°, 1·614°, and 2·169°, corresponding with the mol. depressions 52·0, 51·5, 52·9, and 54·3 respectively. R. Peters showed that soln. with 0·5, 0·25, 0·125, and 0·0625 eq. FeCl₂ per litre gave values corresponding with the mol. wts. 45·7, 44·8, 45·5, and 43·1 respectively; and with the percentage ionizations 93, 95, 91, and 98 respectively. All this is in agreement with a high degree of ionization: $\text{FeCl}_2 \rightleftharpoons \text{Fe}^{++} + 2\text{Cl}'$ of the salt in aq. soln. N. Sasaki studied the effect of potassium iodide, and ferric chloride on the lowering of the f.p. of aq. soln. of ferrous chloride; and W. Biltz and J. Meyer, the relation between the mol. lowering of the f.p., and the heat of soln.

J. Davy, H. Davy, and W. Hampe observed that anhydrous ferrous chloride melts at a red-heat. K. Honda and T. Ishiware gave 670° for the **melting-point**, and A. Ferrari and co-workers 673° to 674°. A. Ferrari discussed the relation between the m.p. and the space-lattice. C. G. Maier observed the **vapour pressure**, *p* mm., of anhydrous ferrous chloride at

	699°	762·4°	807·6°	859·7°	908·7°	951·0°	994·9°
<i>p</i>	12·2	36·3	57·4	126·8	230·5	371·4	593·0

No **thermal dissociation** was observed at temp. up to 1000°, although H. Wolfram said that during the sublimation of ferrous chloride, some ferric chloride is formed by the partial decomposition of the ferrous chloride. V. Meyer, and V. and C. Meyer represented the action $3\text{FeCl}_2 = 2\text{FeCl}_3 + \text{Fe}$. V. Meyer added that no dissociation occurs if the salt be sublimed in an atm. of hydrogen chloride; and L. F. Nilson and O. Pettersson observed no decomposition at 1300° to 1500° in an atm. of hydrogen chloride. P. A. von Bonsdorff found that the crystals of the tetrahydrate effloresce rapidly forming a white powder when they are kept over conc. sulphuric acid; and P. Sabatier observed that when kept for 3 months in vacuo, over conc. sulphuric acid, at 20°, the dihydrate is formed. A. Johnsen said that the crystals of the tetrahydrate become turbid at 40°. A. Reimann observed that the tetrahydrate "fuses in its water of crystallization"; but, according to A. Étard, the tetrahydrate does not melt when heated, but passes into the dihydrate above 90°, and loses its water of crystallization at 120°; A. Gorgeu, however, observed that when heated in an atm. of moist hydrogen, the tetrahydrate melts and it then

contains anhydrous ferrous chloride along with some ferrous oxychloride. According to J. J. Berzelius, when the tetrahydrate is heated in a retort, it first melts in its water of crystallization, then decomposes with the evolution of hydrogen chloride, water, and the vapour of ferric chloride, and when the temp. attains the softening-point of glass, white or colourless ferrous chloride sublimes, and a basic ferrous chloride remains in the retort. The sublimate is yellow owing to the presence of a little ferric chloride. H. Lescœur observed that the **dissociation pressure** of the tetrahydrate is 120 to 130 mm. at 70° ; and that the press. falls abruptly to 2 mm. at 70° as the tetrahydrate passes into the dihydrate. The vap. press. of the dihydrate at 90° , 110° , and 125° is 30, 75, and 188 mm. respectively. The dissociation press. falls from about 130 mm. at 120° to about 17 mm. as the dihydrate passes into the monohydrate; and the dissociation press. of the monohydrate is about 55 mm. at about 155° when it passes into the anhydrous chloride. H. Lescœur observed the vap. press., p mm., of sat. aq. soln. of ferrous chloride to be:

	40°	50°	60°	70°	80°
p	30	56	88	127	177 mm.

and for the mono- and di-hydrates:

	90°	100°	110°	120°	125°	155°
p	30	48	75	130	188	55
	$2\text{H}_2\text{O}$					H_2O

G. Tammann found the lowering of the vap. press., δp mm., of soln. of 4.03, 24.05, 51.90, and 90.54 grms. of FeCl_2 in 100 grms. of water to be respectively $\delta p=10.3$, 79.9, 200.1, and 341.8 mm. Observations on the subject were made by M. Prud'homme.

J. Davy, and H. Davy said that anhydrous ferrous chloride does not volatilize at the softening temp. of glass, but J. J. Berzelius obtained marked **volatilization** at this temp., and V. Meyer said that it volatilizes slowly at a red-heat, and rapidly at a yellow-heat. L. F. Nilson and O. Pettersson observed a rapid volatilization of the salt in an atm. of hydrogen chloride between 1300° and 1500° . C. G. Maier extrapolated his vap. press. data, and obtained 1023.4° for the **boiling-point** of anhydrous ferrous chloride; and calculated 32.11 Cals. per mol for the heat of vaporization at 1023° and 1 atm. press., and at 674.4° and 0.01 atm. press. R. Kremann and F. Noss, and F. Schimmel said that a sat. soln. with 50.4 per cent. of FeCl_2 boils at 117.5° .

P. A. Favre and J. T. Silbermann gave for the **heat of formation** of anhydrous ferrous chloride, $(\text{Fe}, \text{Cl}_2)=49.651$ Cals., but, according to J. Thomsen, this datum is too low, owing to an incorrect value for the heat of soln. having been employed in the calculation. J. Thomsen gave 82.05 Cals.; M. Berthelot, 82.20 Cals.; W. Biltz and C. Fendius, 82 Cals.; and K. Jellinek and R. Koop, 69.13 Cals. J. Thomsen also gave $(2\text{FeCl}_3, \text{Fe})=54.07$ Cals., and M. Berthelot, 54.6 Cals. J. Thomsen gave $(\text{Fe}_{\text{solid}}, \text{Cl}_2, 4\text{H}_2\text{O}_{\text{liq}})=97.20$ Cals. at 18° ; $(\text{FeCl}_2, 4\text{H}_2\text{O}_{\text{liq}})=15.15$ Cals. at 18° ; and P. Sabatier gave $(\text{FeCl}_2, 2\text{H}_2\text{O}, 2\text{H}_2\text{O}_{\text{solid}})=2.52$ Cals. at 20° , and $(\text{FeCl}_2, 2\text{H}_2\text{O}_{\text{solid}})=6.40$ to 6.92 Cals. T. Andrews gave for the heat of formation of ferrous chloride in soln. $(\text{Fe}, \text{Cl}_2, \text{Aq.})=99.1$ Cals.; J. Thomsen, 102.06 Cals.; and M. Berthelot, 99.95 Cals. According to J. Thomsen, P. A. Favre and J. T. Silbermann's value, 53.35 Cals., is too low. J. Thomsen also gave $(\text{Fe}, 2\text{HCl Aq.})=23.42$ Cals.; $(2\text{FeCl}_3 \text{Aq.}, \text{Fe})=44.41$ Cals.; and M. Berthelot, 44.6 Cals. The subject was discussed by E. Rabinowitsch and E. Thilo, and O. Schütz and F. Ephraim. J. Thomsen gave $\{\text{Fe}, 2(\text{HCl}+50\text{H}_2\text{O})\}=21.31$ Cals. J. Thomsen stated that the heats of soln. of iron in hydrochloric, hydrobromic, and hydriodic acids are nearly the same. T. W. Richards and co-workers observed $\{\text{Fe}, n(\text{HCl}+8.8\text{H}_2\text{O})\}=20.55$ Cals.; and $\{\text{Fe}, 2(\text{HCl}+200\text{H}_2\text{O})\}=20.8$ Cals. J. Thomsen gave for the **heat of neutralization** of ferrous hydroxide by hydrochloric acid, $(\text{Fe}(\text{OH})_2, 2\text{HCl Aq.})=21.39$ Cals., and he added that an earlier determination by P. A. Favre and J. T. Silbermann is too low; M. Berthelot obtained

21.4 Cals. for the heat of neutralization with 0.25*N*-HCl. According to M. Berthelot, the action of 2KOH on (FeCl₂.Aq., H₂SO₄ dil. soln.)=1.1 Cals.; and on (FeSO₄.Aq., 2HCl dil. soln.)=2.5 Cals. J. Thomsen found for the **heat of solution**, (FeCl₂.Aq.)=17.9 Cals. at 18.2°, and he added that an earlier determination by P. A. Favre and J. T. Silbermann is too low. J. Thomsen gave 2.75 Cals. for the heat of soln. of 16.58 grms. of the tetrahydrate in about 600 grms. of water at 19.3°; P. Sabatier gave (FeCl₂.4H₂O, 600H₂O)=3.32 Cals. at 17.5°; (FeCl₂.Aq.)=2.7 Cals.; (FeCl₂.2H₂O, 1000H₂O)=8.72 Cals. at 20°; and (FeCl₂.2H₂O, 300 to 600 H₂O)=8.7 Cals. at 20°. O. Schütz and F. Ephraïm discussed the relations between the heat of formation and the mol. vol.; and F. Braun, and G. Beck, the **free energy** of formation of ferrous chloride; G. Devoto and A. Guzzi gave 40,200 cals. at 700°; 37,100 cals. at 750°; 32,500 cals. at 800°; and 27,150 cals. at 850°. G. Beck, and W. Herz calculated values for the **entropy** and vibration frequency of FeCl₂. R. Audubert studied the energy of the reaction Fe⁺⁺→Fe⁺⁺⁺; and M. Randall and M. Frandsen gave -20,310 cals. for the free energy of the ferrous ion. W. Hieber and E. Levy studied the **lattice energy** of the crystals.

G. Limann, and A. Heydweiller measured the **indices of refraction**, μ , of aq. soln. of ferrous chloride at 18°; and G. Limann gave for soln. with *C* equivalents of ferrous chloride per litre:

<i>C</i>	0	0.5	1.0	2.0	4.0
μ_{H_α} -line	1.33139	1.33849	1.34546	1.35881	1.38448
μ_{D} -line	1.33322	1.34038	1.34742	1.36092	1.38682
μ_{H_β} -line	1.33737	1.34473	1.35199	1.36588	1.39241
μ_{H_γ} -line	1.34060	1.34805	—	—	—

W. A. Wooster studied the relation between the refractive index and the lattice structure. The **molecular refraction** for Na-light by the μ^2 -formula is 19.23 at 18°; and A. Heydweiller obtained for very dil. soln. to soln. with 4 eq. of FeCl₂ per litre values ranging from 19.34 to 19.12—average 19.23. Let $\delta\mu$ denote the difference between the value of μ for a soln. of conc. *C* eq. per litre, and water, G. Limann obtained for *D*- and *H α* -light, at 18°, the dispersion $10^5(\delta\mu_D - \delta\mu_a)/C = 14.4$; and for *H β* - and *D*-light, $10^5(\delta\mu_\beta - \delta\mu_D)/C = 38.6$. A. Heydweiller also studied this subject.

J. S. F. Pagenstecher observed that aq. soln. of anhydrous ferrous chloride are at first colourless, but they soon become green when exposed to the air; and A. Étard observed that if a green sat. soln. be heated in a sealed tube at 240°, it becomes colourless. H. M. Vernon studied this subject. W. J. Russell and W. J. Orsman said that soln. of ferrous chloride in hydrochloric acid show no absorption bands in the visible **spectrum**. J. S. Anderson found the **molecular extinction coefficient** *k* of soln. with *C*=4 mols per litre:

λ	4340	5470	6250	7460	8370	9680	11,750	1300 A.
<i>k</i>	0.75	0.025	0.042	0.115	0.17	0.89	1.00	0.84

and for the effect of concentration, with $\lambda=4530$ A., and 6530 A.:

4530 A.					6530 A.			
<i>C</i>	4.0	2.0	1.0	0.5	4.0	2.0	1.0	0.5
<i>k</i>	0.39	0.18	0.16	0.22	0.057	0.067	0.082	0.12

Observations on the subject were also made by J. von Koczkas, and R. A. Houstoun and C. Cochrane. According to R. Zsigmondy, the percentage **transmission of heat rays**, *H*, from an Argand burner through layers 9.5 mm. thick of hydrochloric acid soln. of *C* mols of FeCl₂ per litre, is as follows:

<i>C</i>	2	1	0.5	0.25	0.125	0.0625	0.03125	0
<i>H</i>	1.16	1.85	4.06	6.73	8.95	10.31	10.93	12.2 per cent.

and with different ferrous salts, the results are the same with soln. containing the same proportion of ferrous iron. The high degree of absorption makes the soln. suitable for filtering out the heat rays. S. M. Karim and R. Samuel studied

the **absorption spectrum**. A. Byk and H. Jaffe found that soln. containing 2.53, 1.27, 0.51, and 0.12 grms. of FeCl_2 in 100 c.c. of dil. hydrochloric acid, in layers 1 cm. thick, have limits of absorption with ultra-violet light of wavelength 2735, 2566, 2351, and 2322 respectively. M. N. Saha and S. C. Deb examined the absorption spectrum of the vapour at 1000° to 1400° . O. Stelling, and S. Aoyama and co-workers studied the absorption of the K-series of the **X-ray spectrum** by anhydrous and tetrahydrated ferrous chloride; and A. Hébert and G. Raynaud, the absorption of X-rays by aq. soln. of ferrous chloride. G. Reboul and E. Bodin found that, unlike ferrous sulphate, ferrous chloride emits no radiations when it is connected with the poles of a battery of 2500 volts. M. E. Verdet showed that the mol. **magnetic rotation** of the plane of polarized light for 16.0 and 28.3 per cent. soln. of ferrous chloride is respectively -0.82 and -0.94 . Observations were also made by E. Becquerel, and O. Schönrock. H. Becquerel found for sodium light with soln. containing 0.5283, 0.2641, 0.1320, and 0.0660 grm. of FeCl_2 per 100 c.c., at 15° to 18° , the respective sp. gr. 1.4331, 1.2141, 1.093, and 1.0548; the relative magnetic rotation, for the sodium-line, respectively 0.195, 0.765, 0.908, and 0.954, and the respective magnetic rotations -1.343 , -0.701 , -0.528 , and -0.521 . F. Allison and E. J. Murphy studied the magneto-optic properties; P. Krishnamurti, the **Raman effect**, and O. Stelling, the **X-ray spectrum**—K-series. G. Dima found that the **photoelectric effect** is greater than it is with ferric chloride; and A. Pochettino, similarly with Hallwachs' effect. G. C. Schmidt examined the nature of the charged particles emitted when the salt is heated, and found them to be of atomic dimensions.

A. C. Becquerel found that with a static **electric discharge**, ferrous chloride passes from the negative to the positive pole. G. C. Schmidt, and H. Querengässer measured the **electrical conductivity** of the iron halides in flames. W. Hampe observed that molten anhydrous ferrous chloride is a good conductor; G. Vicentini measured the eq. electrical conductivity, λ mho, of soln. of ferrous chloride containing C eq. per litre at 18° , for C up to 0.0038, and A. Heydweiller for larger values of C , found:

C	.	.	0.00101	0.0038	0.05	1.0	2.0	4.0	6.0
λ	.	.	76	73	69.5	60.6	48.11	30.84	18.13

Observations were also made by G. Limann; C. Cattaneo, and W. Jufereff measured the molar conductivity; and R. Peters, F. Förster, and O. Mustad, the sp. conductivity. G. Limann discussed the relation between the electrical conductivity and light refraction of the soln. For the **ionization** of the soln., *vide supra*, lowering of the f.p. of aq. soln. A. Günther-Schulze discussed the dissociation of the salt in aq. soln. A. Stepniczka-Marinkovic found the **transport number** of the Fe^{++} -ion in 0.988*N*-, 0.494*N*-, and 0.172*N*- FeCl_2 to be respectively 0.300, 0.326, and 0.375; by extrapolation, these data gave 0.414 for the transport number at infinite dilution. It was estimated that in 0.172*N*- FeCl_2 , acidified with a little hydrochloric acid, at room temp., the **solvation** of the anion corresponds with 21 mols. of water, and of the cation, Fe^{++} , with 60 mols. of water. The subject was studied by G. H. Cartledge; and the electro-deposition of iron from the fused chloride, by A. H. W. Aten and co-workers.

E. Petersen found the **electromotive force** of the cell $C | 2N\text{-FeCl}_2, 20 \text{ per cent. NaCl} | \text{Zn}$ to be 1.290 volts; and C. Winther studied the e.m.f. of the cell $\text{Pt} | \text{FeCl}_2, \text{HgCl}_2, \text{Hg}_2\text{Cl}_2 | \text{FeCl}_2, \text{HgCl}_2 | \text{FeCl}_2, \text{HgCl}_2, \text{FeCl}_3 | \text{Pt}$ with different concentrations of the soln. of ferrous chloride. G. Tammann discussed the e.m.f. of the Daniell type of cell with the fused chloride. G. Tammann and E. Jenckel found the effect of a press., p kgrms. per sq. cm., on the e.m.f., E volt, of a hydrochloric acid soln. of ferrous chloride in the cell $\text{Pt} | 0.1N\text{-HCl}, \text{FeCl}_2 | 0.1N\text{-HCl}, \text{Hg}_2\text{Cl}_2 | \text{Hg}$, to be, at 18° :

p	.	.	1	100	500	1000	1500	2000
E	.	.	0.2816	0.2782	0.2738	0.2705	0.2674	0.2643
$dE/p \times 10^3$.	.	-34.0	-9.0	-15.6	-11.1	-9.5	-8.7

G. Tammann and H. O. von Samson-Himmelsjerna studied the potential of iron against ferrous chloride. E. Bouty showed that if two iron electrodes dip in soln. of ferrous chloride of the same conc., but different temp., a thermoelectric current is developed, and the warm soln. acts as a positive pole; the e.m.f. is of the order 0.0477 volt; it is proportional to the difference of temp., but is not perceptibly influenced by differences in concentration. L. Riety found a potential difference is developed between a soln. of ferrous chloride passing through a capillary under a press. of 25 atm., and the walls of the tube. The soln. acquires a negative charge. F. Finkelstein measured the polarization capacity of iron in soln. of ferrous chloride. N. Kameyama and K. Takahashi studied the electro-oxidation of the salt. E. Fossatti observed that the electrolysis of a soln. of ferrous chloride is not influenced by a magnetic field; and A. Schükareff observed that in the electrolysis of a soln. of ferrous chloride in a magnetic field of 2000 to 7000 gauss, about the anode, a magnetochemical effect similar to but not identical with the Hall effect occurs. O. Milicka and A. Slama, and R. Fürth measured the **dielectric constants** of soln. of the salt.

M. Faraday found anhydrous ferrous chloride to be paramagnetic. G. Wiedemann observed that the mol. **magnetism** of ferrous chloride is less than that of ferric chloride, and is only a little different from the hydrates or aq. soln. if equal proportions of iron be considered. C. Matteucci said that ferrous chloride shows no remanent magnetization. T. Ishiwara, and K. Honda and T. Ishiwara gave for the **magnetic susceptibility** at different temp.:

	-182.1°	-101.7°	-24.6°	16.5°	193.9°	410.8°	692.3°
$\chi \times 10^6$	449.0	187.4	122.0	101.2	61.4	39.1	22.9

The value of χ between -190° and 400° changes in accord with the formula $\chi(T + \text{constant}) = \text{constant}$. H. R. Woltjer and E. C. Wiersma also showed that the formula $\chi(T - 20.4) = \text{constant}$ applies down to -210° , but below this temp., the susceptibility is dependent on the intensity of the field, a result opposite to that which holds at a higher temp. O. N. Trapeznikowa and L. W. Shubnikoff studied the Curie point. K. Honda and T. Ishiwara gave for the magnetic moment of a single molecule 4.67×10^{-20} . C. Matteucci found that the tetrahydrate shows no remanent magnetization. T. Ishiwara, and K. Honda and T. Ishiwara gave for the magnetic susceptibility, χ , at different temp.:

	-181.2°	-99.6°	-39.3°	19.4°	107.3°	216.1°	400.4°	685.3°
$\chi \times 10^6$	210.0	101.9	76.0	60.1	50.4	46.8	30.8	17.3

When the tetrahydrate is heated, K. Honda and T. Ishiwara said that the water in the substance separates out at four different ranges of temperatures, 25° to 50° , 105° to 115° , 150° to 160° , and 215° to 240° . The first small diminution of the weight may be an effect of the moisture, the second is due to the separation of two mols. of water, the third and the fourth are due to the separation of one or both mols. of water.

M. Faraday observed that aq. soln. of ferrous chloride are paramagnetic. C. Matteucci observed no evidence of any remanent magnetization, and no evidence of any enrichment of the soln. in iron salt in the vicinity of a magnetic pole. Observations on the magnetic susceptibility were made by J. Plücker, G. Piaggese, O. Wylach, E. Becquerel, H. Fahlenbrach, E. C. Wiersma, and H. W. Eaton. G. Quincke gave 89×10^{-6} at 19° ; J. S. E. Townsend, 91×10^{-6} at 10° , and G. Jäger and S. Meyer, 61×10^{-6} at 18° . The mol. magnetic susceptibilities observed by A. Quartaroli for soln. with a mol of FeCl_2 in v litres, at 18° , were:

v	10	20	50	100	250	500	750
$\chi \times 10^6$ (mol)	11,841	11,500	11,455	10,944	10,840	10,638	10,496

Observations on the influence of the conc. of the soln. were made by J. Plücker, G. Wiedemann, J. S. E. Townsend, H. Fahlenbrach and E. Vogt, E. Vogt, C. J. Gorter, A. Quartaroli, and P. Théodorides, and the results show that the

mol. magnetic susceptibility decreases slowly with dilution. A. Heydweiller observed very little change in passing from the tetrahydrate to the soln. G. Wiedemann, G. Quincke, and J. S. E. Townsend measured the effect of temp., and the last-named found that the susceptibility falls linearly as the temp. is increased. G. Quincke, H. E. J. G. du Bois, J. S. E. Townsend, R. H. Weber, and A. Heydweiller found that small changes in the magnetic field-strength have very little influence on the susceptibility. H. Fahlenbrach discussed the magnetic moment. A. Quartaroli, L. Pauling and M. L. Huggins, and G. Foëx calculated values for the magneton number.

S. S. Bhatnagar and co-workers observed that paramagnetic iron salts become diamagnetic when adsorbed on charcoal, thus showing that the process of adsorption is more akin to chemical combination than to admixture. According to G. Roasio, the magnetic field exercises an influence on (1) the orientation of the crystals, the angles between axes and lines of force varying with the substance, but being constant for a given compound; and (2) the growth of the crystals, which become elongated in a definite direction, the angles remaining constant, but again varying with the substance.

The chemical properties of ferrous chloride.—According to E. Péligot, anhydrous ferrous chloride is reduced to metal when it is heated in dry **hydrogen**; and V. and C. Meyer observed a partial reduction when the chloride is sublimed in hydrogen. W. Spring, and H. Wolfram also observed the reduction of the chloride to the metal. W. Biltz and F. Meyer gave $\text{FeCl}_3 \cdot \text{Aq.} + \frac{1}{2} \text{H}_2 = \text{FeCl}_2 \cdot \text{Aq.} + \text{HCl} \cdot \text{Aq.} + 10.3 \text{ Cals.}$ F. Schmitz said that the reduction occurs at 300° to 400° ; and A. Smits and co-workers obtained pyrophoric iron by reducing the chloride at 350° . P. Schützenberger thought that a volatile hydrochloride, FeHCl , or $\text{FeCl}_2 \cdot n\text{HCl}$, is formed, but this has not been confirmed. A. B. Bagdasarian studied some equilibrium conditions in the reaction $\text{FeCl}_2 + \text{H}_2 \rightleftharpoons 2\text{HCl} + \text{Fe}$, with fused ferrous chloride, and found $K = p_{\text{HCl}}^2/p_{\text{H}_2}$, and obtained the following values of K and percentages of hydrogen chloride, and hydrogen in the gases:

	$\text{FeCl}_2 + \text{H}_2$				$\text{Fe} + 2\text{HCl}$	
	702°	800°	925°	932°	725°	1005°
K	0.064	0.297	0.767	0.813	0.11	1.63
HCl	22.0	41.6	57.3	58.4	28.2	69.5 per cent.
H_2	78.0	58.4	42.7	41.6	71.8	30.5 „

The breaks in the curve for $\log K$ and $T^{-1}^\circ K$ are supposed to be due to allotropic transformations in the iron. K. F. Bonhöffer observed no reaction between ferrous chloride and activated hydrogen. B. Neumann observed that the aq. soln. is not reduced by hydrogen in the presence of platinum.

According to J. L. Gay Lussac, if **oxygen** be passed over molten ferrous chloride, chlorine and ferric oxide are formed; and if the supply of air be restricted, some ferric chloride is produced. *Vide supra* for the oxidation of soln. of ferrous chloride in connection with the oxidation-reduction potential of iron salts. H. Schulze, and S. I. Levy and G. W. Gray represented the reaction of oxygen or dry **air** on heated ferrous chloride: $12\text{FeCl}_2 + 3\text{O}_2 = 8\text{FeCl}_3 + 2\text{Fe}_2\text{O}_3$; and if a small proportion of ferrous chloride is employed, some chlorine is formed, and some ferric chloride is always produced and volatilized when ferrous chloride is so oxidized. S. I. Levy and G. W. Gray found that at 250° , in air—dry or moist—hydrated ferrous chloride rapidly forms ferric oxide and hydrogen chloride. A. Gorgen obtained crystals of ferric oxide by melting ferrous chloride in air at dull redness, and crystals of ferrosic oxide at a cherry-red-heat; in the latter case, the vapour of ferrous chloride protects the salt from a vigorous attack by oxygen. J. S. F. Pagenstecher observed that when white ferrous chloride is exposed to air, it first becomes matt, then greenish-yellow, and finally reddish-brown. J. Schabus also made some observations on this subject, and H. Wolfram added that anhydrous ferrous chloride is less hygroscopic than ferric chloride. P. A. von Bonsdorff also noted that the light

blue crystals of the tetrahydrate become grass-green on exposure to air, and then acquire a yellowish-brown opaque film; the tetrahydrate is deliquescent, but it effloresces in dry air over 50° . P. Nicolardot, and F. Tommasi discussed the nature of the yellowish-brown, hydrated ferric oxide which is formed during the aerial oxidation of ferrous chloride. C. F. Rammelsberg obtained crystals of ferrous oxide by passing air and **water** vapour over red-hot ferrous chloride, and E. A. Parnell, crystals of ferric oxide. H. Frischer said that the reaction is almost complete in 1 to $1\frac{1}{2}$ hrs. at 250° . J. L. Gay Lussac represented the reaction with water vapour: $3\text{FeCl}_2 + 4\text{H}_2\text{O} = \text{Fe}_3\text{O}_4 + 6\text{HCl} + \text{H}_2$. Analogous observations were made by E. A. Parnell, F. Konther, and A. Gautier. H. W. Fischer observed that when a soln. of the chloride is heated in a sealed tube at 210° , black plates are deposited. According to H. Precht, the reaction between steam and ferrous chloride at a comparatively low temp., in geological periods, resulting in the formation of hydrogen and ferric oxide, explains the presence of hydrogen in the carnallite deposits of Stassfurt; and E. Erdmann observed that hydrogen is formed when ferrous chloride and water are heated 160 hrs. at 100° to 120° . H. Precht, and E. Pfeiffer represented the action of water on ferrous chloride or douglasite by $6\text{FeCl}_2 + 3\text{H}_2\text{O} = 4\text{FeCl}_3 + \text{Fe}_2\text{O}_3 + 3\text{H}_2\text{O}$. The reaction was studied by H. E. Boeke, and H. Ditz. G. Schikorr found that ferric oxide and iron turnings at room temp. act on water with the evolution of hydrogen; and that water is decomposed by ferrous hydroxide. W. Traube and W. Lange found that ferrous hydroxide in the presence of finely-divided palladium and water, develops hydrogen when heated. R. Phillips observed that when an aq. soln. of ferrous chloride is exposed to air, it is hydrolyzed, and the ferrous hydroxide is oxidized by air to hydrated ferric oxide which is precipitated. The solubility of ferrous chloride in water has been previously discussed—Fig. 560. According to F. Jahn, the hydrolysis is indicated by the reddening of litmus by the aq. soln.; but C. C. Ahlum observed that the aq. soln. is neutral towards methyl orange. J. H. Long found the degree of hydrolysis of $0.5N\text{-FeCl}_2$ at 85° , from its action on the inversion of cane-sugar, to be 0.063 per cent. H. Zocher and W. Heller observed the slow hydrolysis of 0.1 to 8 per cent. soln. of ferrous chloride resulting in the deposition of anisotropic layers. E. Deiss and G. Schikorr said that the degree of hydrolysis is too small to be detected when the soln. diffuses through a membrane. The autoxidation of soln. of ferrous salts was studied by H. Wieland and W. Franke, using sodium acetate and acetic acid as a buffer. Absorption of oxygen follows the unimolecular law. The temp. coeff. of the process is normal, whilst a change from $p_{\text{H}}=5$ to 7 accelerates the reaction 4- or 5-fold. At $p_{\text{H}}=5$, neutral salts have little effect on the rate of autoxidation, although sodium sulphate, possibly owing to its producing complex salts, causes diminution of the reaction velocity to half its previous value. The rate of autoxidation of slightly hydrated ferrous chloride is greater in acetone than in ethyl alcohol or isopropyl alcohol, greater in these solvents than in methyl alcohol, and least in water. R. Thomas and E. T. Williams studied the catalytic influence of nitric oxide on the oxidation of a soln. of ferrous chloride in air, and found the reaction agrees with $Kt=x(a-\frac{1}{2}x)$. The rate is proportional to the initial conc. of the ferrous salt; is approximately proportional to the conc. of the catalyst; is independent of the conc. of the hydrochloric acid; and increases 1.8-fold per 10° rise of temp. J. C. Duff and E. J. Bills obtained **ferrous hydroxytrichloride**, $\text{Fe}_2(\text{OH})\text{Cl}_3$, by the action of hexamethylenetetramine on ferrous chloride; and E. Hayek, $\text{Fe}(\text{OH})\text{Cl}$, by boiling a 45 to 50 per cent. soln. of ferrous chloride with iron powder, and washing the product with alcohol. W. Feitknecht found that the space-lattice of $\text{FeCl}_2 \cdot 4\text{Fe}(\text{OH})_2$ corresponds with alternate layers of the normal salt and the hydroxide. For the action of **hydrogen dioxide**, see the iron peroxides, and ferric chloride. A. K. Goard and E. K. Rideal, D. R. Hale, W. C. Bray and M. H. Gorin, H. Wieland and W. Franke, and S. Goldschmidt and S. Pauncz studied the catalytic effect of ferrous salts on the oxidizing action of hydrogen dioxide. According to A. Simon and K. Kötschau,

5 to 10 c.c. of a 0.5 per cent. alcoholic soln. of guaiacum resin per 250 c.c. of water, are coloured blue by 5.6×10^{-6} grm. of ferrous iron in presence of hydrogen dioxide in 1 litre of neutral soln., and by 6.8×10^{-5} grm. in a slightly acid soln. The best results are obtained by adding the hydrogen peroxide to the mixture of ferrous salt and guaiacum soln. Light should be excluded, and appreciable amounts of acetic or hydrochloric acid interfere, whereas alkaline soln. do not give the test at all. If "ferrum reductum" is ground up in a mortar, it commences to give the benzidine and guaiacum resin reactions, ferrous hydrogen carbonate being formed by atmospheric moisture and carbon dioxide. By filtration of a suspension of the activated preparation through a membrane filter, an active liquid is obtained, but this gradually loses its activity, the activity towards benzidine and guaiacum resin being a function of the ferrous-ion concentration. By filtering a suspension of ferrum reductum in oxygen-free water saturated with carbon dioxide through a membrane-filter, a liquid results which is active, and retains its activity for weeks, even if light is not excluded, provided that it is kept out of contact with air. The effect of ultra-violet radiation is very slight so long as air is carefully excluded. It is concluded that the activity of natural waters containing iron depends on the presence of ferrous iron, and when this is oxidized the activity disappears. The subject was studied by J. Weiss.

O. Ruff and E. Ascher showed that **fluorine** reacts with ferrous chloride in the cold, and much heat is evolved in the reaction. J. Davy observed that the reaction with **chlorine** is quantitative: $2\text{FeCl}_2 + \text{Cl}_2 = 2\text{FeCl}_3$; and E. Busch observed a similar reaction with ferrous chloride and a soln. of chlorine in methylal. Chlorine also acts as an oxidizing agent in converting ferrous chloride in aq. soln. into ferric chloride (*q.v.*). E. Busch observed that **bromine**, like chlorine, has an oxidizing action on ferrous chloride; and the reaction was studied by V. Rodt and K. Charisius. C. Lenormand found that bromine reacts with ferrous chloride so slowly that the reaction is not completed in a month; when the mixture is heated at 100° in a sealed tube for 24 hrs., a sublimate of ferric bromodichloride is formed. A. W. Francis found that the reaction of bromine on ferrous chloride and sulphate at 25° proceeds at about the same rate. W. D. Bonner and H. Romeyn, and E. Busch observed that **iodine**, like bromine, acts as an oxidizing agent on ferrous chloride in acidic soln. in the presence of phosphoric acid—*vide infra*, ferrous sulphate, and ferric chloride. J. Lifschitz and S. B. Hooghoudt studied the photochemistry of the reaction. G. B. Heisig represented the reaction with **iodine chloride**, $2\text{FeCl}_2 + 2\text{ICl} = \text{I}_2 + 2\text{FeCl}_3$. E. C. Franklin found that anhydrous ferrous chloride is insoluble in liquid **hydrogen fluoride**; K. Fredenhagen and G. Cadenbach studied the action of **hydrofluoric acid** on the salt; and K. Fredenhagen added that chlorine is developed. W. Peters observed that the anhydrous salt does not absorb **hydrogen chloride**. V. Meyer, and L. F. Nilson and O. Pettersson observed no chemical change when ferrous chloride is sublimed in an atm. of hydrogen chloride. P. Sabatier observed that the tetrahydrate is soluble in **hydrochloric acid**, but less than is the case with water. H. Lescœur, and P. Sabatier—*vide supra*—showed that when hydrogen chloride is passed into an aq. soln. of ferrous chloride, the hexahydrate or tetrahydrate may be precipitated; and when the soln. is sat. with the gas, the dihydrate is formed. J. Wagner assumed that a *ferrous hydrochloride* is formed in soln. of ferrous chloride in hydrochloric acid, but S. R. Carter and N. J. L. Megson, and T. W. Harrison and F. M. Perkin could not confirm this. W. Preiss studied the influence of ferrous salts on the reduction of **iodides** by chromic acid; and A. K. Goard and E. K. Rideal, W. J. Husa and L. Magid, A. Berthoud and S. V. Allmen, and S. V. Allmen, on the liberation of iodine from iodides and hydrogen dioxide. J. Thomsen represented the oxidation with **hypochlorous acid**: $2\text{FeCl}_2 \cdot \text{Aq.} + 4\text{HCl} \cdot \text{Aq.} + \text{HOCl} \cdot \text{Aq.} = 2\text{FeCl}_3 \cdot \text{Aq.} + 3\text{HCl} \cdot \text{Aq.} + 54.993 \text{ Cals.}$ J. L. Gay Lussac, and H. Schulze showed that when ferrous chloride is fused with **potassium chlorate**, the products—chlorine and ferric oxide—are similar to those obtained when the chloride is heated in

oxygen. I. M. Kolthoff, O. Collenberg and K. Sandved, and W. Meyerhoffer noted the oxidation of ferrous chloride to ferric chloride by **bromic acid**, or **potassium bromate**.

A. Vogel observed that no iron sulphide is formed when ferrous chloride is heated with **sulphur**. A. W. Ralston and J. A. Wilkinson observed that ferrous chloride is not dissolved by liquid **hydrogen sulphide** at a low temp., or at room temp. The aq. soln. is not reduced by hydrogen sulphide—*vide* ferric chloride. H. de Sénarmont found that when ferrous chloride is heated with **potassium polysulphide** in a sealed tube at 180°, pyrite, FeS_2 , is formed. According to J. A. Smythe and W. Wardlaw, and W. Wardlaw and F. H. Clews, ferrous chloride in a strongly acid soln. is oxidized to ferric chloride by **sulphur dioxide**: $4\text{FeCl}_2 + \text{SO}_2 + 4\text{HCl} = 4\text{FeCl}_3 + 2\text{H}_2\text{O} + \text{S}$, with the possible intermediate formation of thionyl chloride. The proportion of ferric chloride which is formed is nearly independent of the conc. of the ferrous salt, and increases with rise of temp. up to an optimum. If the soln. has less than 145 grms. HCl per litre, no oxidation occurs; and the maximum oxidation in open vessels was 8·8 per cent. of the total iron, in closed vessels 9·5 per cent. Soln. with 10 to 18 per cent. of the total iron as ferric chloride are neither oxidized nor reduced; and soln. with over 18 per cent. are slowly reduced. D. Richter studied the effect of the presence of ferrous chloride on the oxidation of **sodium sulphite** in aq. soln. A. Vogel, and H. Friedrich observed that with cold **sulphuric acid**, ferrous chloride furnishes hydrogen chloride, and ferrous sulphate. J. Thomsen observed that the heat of neutralization of ferrous hydroxide with sulphuric acid is rather greater than it is with hydrochloric acid, so that a little heat is evolved when a dil. soln. of ferrous chloride is treated with dil. sulphuric acid. G. Lunge observed that yellowish-red selenium is formed when a soln. of ferrous chloride is treated with a sulphuric acid soln. of **selenium dioxide**.

A. Guntz found that **lithium nitride** reacts very energetically when it is warmed with ferrous chloride, and if the vigour of the reaction be abated by admixed sodium chloride, iron nitride is formed; A. Smits also observed a vigorous reaction occurs with **magnesium nitride** resulting in the formation of iron nitride which is decomposed at the high temp. of the reaction. According to M. Faraday, H. V. Regnault, A. W. F. Rogstadius, F. Girardet, E. Frémy, W. Peters, F. Ephraim, G. J. Fowler, A. S. Miller, H. N. Warren, and C. Stahlschmidt, at room temp. ferrous chloride readily absorbs **ammonia** to form a voluminous, white mass of the hexammine; at temp. below 350°, the absorption of ammonia is a reversible process, but above that temp. the reaction is not reversible, and a product is formed containing some iron nitride, whilst ammonium chloride, nitrogen, and hydrogen are evolved. C. Stahlschmidt represented the reaction: $14\text{NH}_3 + 12\text{FeCl}_2 = 4\text{N}_2 + 24\text{HCl} + 6\text{Fe}_2\text{N} + 9\text{H}_2$. Similar reactions occur when the hexammine is heated above 350°. H. Wolfram said that the reaction at 490° to 530° can be represented by the equation: $3\text{FeCl}_2 + 8\text{NH}_3 = 3\text{Fe} + \text{N}_2 + 6\text{NH}_4\text{Cl}$. The metallic iron so formed reacts in part with the nascent nitrogen: $2\text{Fe} + \text{N} = \text{Fe}_2\text{N}$; and in part with ammonia: $4\text{Fe} + 2\text{NH}_3 = 2\text{Fe}_2\text{N} + 3\text{H}_2$. According to W. Biltz and E. Rahlfs, ammonia reacts with ferrous chloride to form four amines— $\text{FeCl}_2 \cdot 10\text{NH}_3$, $\text{FeCl}_2 \cdot 6\text{NH}_3$, $\text{FeCl}_2 \cdot 2\text{NH}_3$, and $\text{FeCl}_2 \cdot \text{NH}_3$. Their ranges of existence at different temp. are shown in W. Biltz's diagram, Fig. 561. The amines are formed by absorption of ammonia as just indicated; K. A. Hofmann and co-workers obtained evidence of the formation of an ammine by the action of ammonium chloride on iron at a high temp.; J. Schröder, by the action of ammonia on a soln. of ferrous chloride in pyridine; and E. Weitz and H. Müller, by the action of an ammoniacal

FIG. 561.—The Dissociation Pressures of the Amines of Ferrous Chloride.

soln. of ammonium chloride on a soln. of a ferrous salt. A. S. Miller observed that the ammonia is absorbed by ferrous chloride more readily than is the case with ferric chloride, and much heat is evolved at the same time, and F. Ephraim and co-workers said that these amines are an exception to the rule that by raising the valency of the central atom, the stability of the amines is raised—here the ferrous chloride amines are more stable than those of ferric chloride. W. Biltz and G. F. Hüttig observed that the strength of the union of the NH_3 -molecule with that of ferrous chloride increases in passing from the hexammine to the diammine to the monammine.

W. Biltz and E. Rahlfs prepared **ferrous decamminochloride**, $\text{FeCl}_2 \cdot 10\text{NH}_3$, by the action of liquid ammonia at -78.5° on anhydrous ferrous chloride. At -78.5° , the dissociation press., p , Fig. 561, is 22 mm.; at -70° , 49.5 mm.; at -65° , 77 mm.; at -60° , 116 mm.; and at -55° , 173 mm. The heat of formation $\text{FeCl}_2 \cdot 6\text{NH}_3 + 4\text{NH}_3$ is 29.0 Cals.—i.e. 7.25 Cals. per mol NH_3 —and this also represents the heat of dissociation. The heat of formation $(\text{FeCl}_2 \cdot 10\text{NH}_3)_{\text{gas}} = 117$ Cals. When the decammine dissociates, it furnishes **ferrous hexamminochloride**, $\text{FeCl}_2 \cdot 6\text{NH}_3$. P. Pfeiffer represented the hexahydrate, the hexammine, and the tridipyridyl-salts, by the formulæ :

F. J. Garrick calculated values for the energy of co-ordination. G. L. Clark discussed the stabilities of the amines. The hexammine was the first ammine to be prepared, as indicated above, by the absorption of ammonia at room temp. W. Biltz and G. F. Hüttig preferred to saturate the anhydrous chloride at a low temp., and evaporate the excess of ammonia at room temp. E. Weitz and H. Müller obtained it as indicated above, and W. Hieber and G. Bader, by the action of ammonia on iron dichlorotetracarbonyl, $\text{Fe}(\text{CO})_4\text{Cl}_2$. According to W. Biltz, and A. Werner, the ammonia in the hexammine is part of the cation $[\text{Fe}(\text{NH}_3)_6]\text{Cl}_2$, and in the molecule, the Fe^{++} -atom is surrounded by an octahedral ring of molecules of ammonia. G. F. Hüttig added that six is the maximum number of ammonia molecules which can be arranged about the central iron atom. W. Biltz and E. Birk also discussed the packing density of the ammonia molecules. All observers agree that the hexammine prepared in the dry way is a voluminous, white or grey powder; and W. Biltz added that it occupies three times the vol. of the original ferrous chloride. E. Weitz and H. Müller added that the white colour is due to the fine state of subdivision of the hexammine, for when prepared in crystals by a wet process, the colour is pale green, and soln. containing the ion $[\text{Fe}(\text{NH}_3)_6]^{++}$ have the same colour. According to W. Biltz, the crystals are cubic, and isomorphous with other hexammines of the iron-family. The X-radiogram shows that the space-lattice has the parameter $a=10.19$ Å. The chlorine atoms are related to the iron atoms like the fluorine atoms are related to the calcium atoms in fluorspar. The centre of a NH_3 -molecule is about $\frac{1}{4}a$ from the middle of a metal atom which is surrounded by an octahedral ring of the ammonia molecules. G. B. Naess and O. Hassel studied the sphere of action of the anion. W. Biltz and E. Birk found the sp. gr. to be 1.428 at $25^\circ/4^\circ$. F. Girardet found the dissociation press., p mm., to be :

	0°	14°	50°	70°	90°	100°	115°
p	0	5	11	93	270	425	743

and F. Ephraim (Fig. 561):

	64.5°	75°	85.5°	100.5°	105.7°	108.8°	115°
<i>p</i>	82	130	203	375	490	547	715

F. Müller gave -18° to 95° for the dissociation temp. **G. Beck** gave 317 cal. for the heat of formation of the hexammine; and **W. Hieber** and **E. Levy** studied the subject. **W. Biltz** and co-workers, and **F. Ephraim** calculated for the heat of formation $(\text{FeCl}_2, 6\text{NH}_{3\text{gas}}) = 87.96$ Cals.—or 14.66 Cals. per mol. NH_3 —and for $(\text{FeCl}_2, 2\text{NH}_3, 4\text{NH}_{3\text{gas}}) = 49.0$ Cals.—or 12.25 Cals. per mol. NH_3 . The maximum work or affinity of the reaction $(\text{FeCl}_2, 6\text{NH}_3)$ at 27° , and atm. press., is 31.08 Cals.—or 5.18 Cals. per mol. of NH_3 . **F. J. Garrick** calculated the energy of co-ordination. **M. Faraday**, **A. S. Miller**, **G. J. Fowler**, and **H. Wolfram** observed that when the white hexammine is exposed to air, it becomes yellow or green, brown, and finally black. The hexammine prepared in a wet way was found by **E. Weitz** and **H. Müller** to decompose in a similar manner on exposure to air. **A. W. F. Rogstadius** observed that when heated out of contact with air, the hexammine sinters and then fuses to a dark brown mass with the composition $3\text{FeCl}_2, 2\text{NH}_3$. **G. B. Naess** and **O. Hassel** observed that the hexammine forms $[\text{Fe}(\text{NH}_3)_6](\text{BF}_4)_2$, and $[\text{Fe}(\text{NH}_3)_6](\text{SO}_3\text{F})_2$.

F. Girardet, **H. Wolfram**, and **W. Biltz** and **G. F. Hüttig** observed that when the hexammine is heated, it passes, without the formation of an intermediate compound, into **ferrous diamminochloride**, $\text{FeCl}_2, 2\text{NH}_3$. **A. S. Miller** recommended heating the hexammine to 100° in a current of hydrogen. **W. Biltz** said that the ammonia of the diammine is associated with the anion, and that the co-ordination number is 4. **F. Girardet** gave for the dissociation press., *p* mm.:

	96°	135°	160°	205°	255°	270°	272°
<i>p</i>	1	5	13	62	378	601	727

but **W. Biltz** and **G. F. Hüttig** said that these values are too high, and they gave $p = 121$ mm. at 230° , and 555 mm. at 277° . **F. Müller** gave 240° to 270° . According to **W. Biltz** and **G. F. Hüttig**, the heat of formation $(\text{FeCl}_2, 2\text{NH}_{3\text{gas}}) = 38.96$ Cals. or 19.48 Cals. per mol. of NH_3 ; and $(\text{FeCl}_2, \text{NH}_3, \text{NH}_{3\text{gas}}) = 18.20$ Cals. The maximum work or affinity of the reaction $(\text{FeCl}_2, 2\text{NH}_3)$ at 27° , and atm. press., is 19.5 Cals.—or 9.75 Cals. per mol. **W. Hieber** and **E. Levy** studied the energy of formation. According to **H. Wolfram**, the diammine passes into **ferrous monamminochloride**, $\text{FeCl}_2, \text{NH}_3$, at 260° , and **W. Biltz** and **G. F. Hüttig** suggested 276.7° . **W. Biltz** said that the ammonia of the monammine is associated with the anion. The dissociation press., *p* mm., was found by **W. Biltz** and co-workers to be 5.8, 10.9, and 54.4 mm. respectively at 214.5° , 230° , and 277° . **H. Wolfram** said that the monammine loses 0.9 mol. of ammonia at 320° . **F. Müller** said over 300° . **W. Biltz** and co-workers gave for the heat of formation $(\text{FeCl}_2, \text{NH}_3) = 20.76$ Cals.; and for the maximum work or affinity, at 27° , and atm. press., 11.06 Cals. **F. Ephraim** and **R. Linn**, and **W. Biltz** and **G. F. Hüttig** also found that ferrous chloride forms **ferrous hexamethylaminochloride**, $\text{FeCl}_2, 6(\text{CH}_3, \text{NH}_2)$; and grey **ferrous dimethylaminochloride**, $\text{FeCl}_2, 2(\text{CH}_3, \text{NH}_2)$, by the action of **methylamine**, in place of ammonia or ferrous chloride. For the action of **hydroxylamine**, *vide* ferric chloride.

H. Goldschmidt and **K. L. Syngros** found that when an excess of **hydroxylamine hydrochloride** and sodium carbonate is added to a soln. of ferrous chloride, the soln. becomes dark red, due, it is thought, to the formation of **ferrous hydroxylaminochloride**, $[\text{Fe}(\text{NH}_2\text{OH})_2]\text{Cl}_2$. **O. von Mayer**, and **H. Franzen** and **O. von Mayer** added **hydrazine hydrate** to a 15 per cent. alcoholic soln. of ferrous chloride, and obtained a brown precipitate; when the mixture is warmed, gas is given off and the yellow, pulverulent **ferrous hydrazinochloride**, $\text{FeCl}_2, 2\text{N}_2\text{H}_4$, is formed. The magnetic properties were examined by **D. M. Bose**, and **P. Ray** and **H. Bhar**. The action of **nitric oxide** on ferrous salts has been previously discussed—8. 49, 35—by **H. I. Schlesinger** and **H. B. van Valkenburgh**. **W. Manchot** and **C. Zechentmayer**, **W. Manchot** and **F. Huttner**, **V. N. Morris**, **T. Graham**, **J. Gay**, **V. Thomas**,

and I. Bellucci. The compounds $\text{FeCl}_2 \cdot \text{NO} \cdot 2\text{H}_2\text{O}$, and $\text{FeCl}_2 \cdot \text{NO}$ first described by V. Thomas were afterwards shown to be wrong. According to V. Thomas, if nitric oxide, free from nitrous oxide, be passed over anhydrous ferrous chloride, a little nitric oxide is absorbed, and the product acquires a red colour—the dark colour observed by T. Graham was due to the presence of some nitrous oxide—if the temp. be in the vicinity of 300° , the product approximates $10\text{FeCl}_2 \cdot \text{NO}$ to $12\text{FeCl}_2 \cdot \text{NO}$. When ferric chloride is reduced by distillation in an atm. of nitric oxide, **ferrous heminitrosylchloride**, $2\text{FeCl}_2 \cdot \text{NO}$, is formed: $2\text{FeCl}_3 + 3\text{NO} = 2\text{NOCl} + 2\text{FeCl}_2 \cdot \text{NO}$; if the ferric chloride be heated in a rapid current of nitric oxide, the reaction is symbolized $\text{FeCl}_3 + \text{NO} = \text{FeCl}_2 + \text{NOCl}$. The heminitrosylchloride is a yellowish-brown powder; decomposed by water; stable in dry air, but decomposed by moist air. When heated in air, it forms ferric oxide, but in nitrogen, it gives off nitric oxide and yields ferrous chloride. H. Müller observed that if an ammoniacal soln. of an ammonium salt and ferrous chloride be treated, in the cold, with nitric oxide, there is formed **ferrous nitrosyl-pentamminochloride**, $[\text{Fe}(\text{NO})(\text{NH}_3)_5]\text{Cl}_2$. The black, octahedral crystals decompose on exposure to air. V. Thomas observed that anhydrous ferrous chloride, at room temp., absorbs dry **nitrous oxide** without oxidation. The absorption is faster than is the case with nitric oxide. The compound approximates **ferrous tetritanitroxylchloride**, $4\text{FeCl}_2 \cdot \text{NO}_2$. If water be present, more nitrous oxide is absorbed, and some chlorine is evolved. The tetranitroxylchloride is black, and it is stable in dry air or in vacuo; it is decomposed by water with the partial oxidation of the iron. The red, aq. soln. forms a black precipitate when treated with alkali. H. Gall and H. Mengdehl found that when **nitrosyl chloride** is passed over ferrous chloride, the mass becomes warm, swells up, and nitric oxide is evolved. There is a reaction $\text{FeCl}_2 + \text{NOCl} = \text{FeCl}_3 \cdot \text{NO}$; then follows the formation of $\text{FeCl}_3 \cdot \text{NOCl}$. At a low temp., ferrous chloride reacts with liquid nitrosyl chloride at -20° to form crystals of $\text{FeCl}_3 \cdot \text{NOCl}$. A. Joly and E. Leidié, and P. Schwarzkopf found that when a soln. of ferrous chloride is treated with **alkali nitrite** until it reacts alkaline, a brown gelatinous precipitate is formed; and J. Thiele observed that on adding a conc. soln. of sodium nitrite to a hydrochloric acid soln. of ferrous chloride, a regular stream of nitric oxide is evolved: $\text{FeCl}_2 + \text{NaNO}_2 + 2\text{HCl} = \text{FeCl}_3 + \text{NaCl} + \text{H}_2\text{O} + \text{NO}$. R. Thomas and E. T. Williams observed that the presence of a little sodium nitrite catalyzes the slow oxidation of a soln. of ferrous chloride by air. Ferrous chloride is oxidized to ferric chloride (*q.v.*) by **nitric acid**. L. H. Milligan and G. R. Gillette, and R. Hac and V. Netuka studied the reduction of nitric acid by ferrous chloride using molybdic acid as catalyst. A. Quartaroli showed that if nitrous acid be removed, nitric acid does not act as an oxidizing agent, so that in presence of carbamide, an amino-acid, or an amide, nitric acid does not oxidize ferrous salts because these agents destroy the nitrous acid.

A. Granger observed that **phosphorus** vapour at dull redness converts ferrous chloride into iron phosphide, Fe_2P_3 . H. Rose observed that ferrous chloride reacts in the cold with **phosphine** forming hydrogen chloride and iron phosphide. W. Peters said that no phosphine is absorbed by anhydrous ferrous chloride. A. W. Cronander observed that **phosphorus pentachloride** acts on warm ferrous chloride forming phosphorus trichloride and $\text{FeCl}_3 \cdot \text{PCl}_5$. H. P. Cady and R. Taft said that ferrous chloride is perceptibly soluble in **phosphoryl chloride**. D. Richter studied the catalytic oxidation of ferrous ions on **hypophosphorous acid**. E. Fischer observed that when a hydrochloric acid soln. of ferrous chloride is heated with **arsenic acid**, volatile arsenic trichloride is formed. H. Sommerlad said that anhydrous ferrous chloride reacts when it is heated with **antimony trisulphide** forming antimony trichloride. A. Béchamp and C. St. Pierre found that **antimony trichloride** is not reduced by a boiling soln. of ferrous chloride; and R. F. Weinland and co-workers obtained a complex salt by the action of **bismuth chloride** on a soln. of ferrous chloride.

N. Schiloff and L. Lepin, and N. Schiloff studied the adsorption of ferrous

chloride from aq. soln. by **carbon**. F. W. O. de Coninck observed that unlike a soln. of ferric chloride, a soln. of ferrous chloride suffers no change when it is filtered through animal charcoal. W. Peters found that anhydrous ferrous chloride absorbs no **carbon monoxide**. By the action of dry chlorine on **iron carbonyl**, $\text{Fe}(\text{CO})_5$, in petroleum ether at -20° , W. Hieber and co-workers prepared **ferrous tetracarbonyl chloride**, $\text{Fe}(\text{CO})_4\text{Cl}_2$; by the action of dry chlorine on mercuric iron carbonyl, $\text{Fe}(\text{CO})_4\text{Hg}$, H. Hock and H. Stuhlmann obtained the same salt. It gives off carbon monoxide slowly if the temp. exceeds 10° , or the press. is below 750 mm. The soln. in nitrobenzene is decomposed on exposure to light; and it is decomposed by water into ferrous chloride and carbon monoxide; with ammonia it forms ferrous hexamminochloride; and with pyridine it forms ferrous pyridinochloride. If the temp. at which the chlorine acts on the pentacarbonyl is very low, **ferrous pentacarbonyl chloride**, $\text{Fe}(\text{CO})_5\text{Cl}_2$, is formed. M. Hannik studied the oxidation of ferrous salts by **potassium ferricyanide**.

W. Manchot and J. Haas said that an aq. soln. of ferrous chloride does not react with **ethylene**. J. Kachler showed that when an ethereal soln. of hydrated ferrous chloride is heated in a sealed tube, colourless, acicular crystals of **ferrous ethylenechloride**, $\text{FeCl}_2 \cdot \text{C}_2\text{H}_4 \cdot 2\text{H}_2\text{O}$, soluble in water, are formed—*vide infra*, ether. V. Thomas observed that ferrous chloride is soluble in **ethylene chloride**, and in **ethylene bromide**—the soln. absorb nitric oxide. W. Peters said that anhydrous ferrous chloride does not absorb ethylene or **acetylene**. V. Thomas observed that ferrous chloride is slightly soluble in **benzene**. Ferrous chloride is soluble in **methyl alcohol**. A. Benrath observed that when a soln. of ferric chloride in methyl alcohol is illuminated, ferrous chloride is formed and the soln. deposits colourless crystals of **ferrous methylalcoholochloride**, $\text{FeCl}_2 \cdot 4\text{CH}_3\text{OH}$. The soln. in methyl alcohol was found by K. A. Hofmann and G. Bugge to be rapidly oxidized by air; V. Kohlschütter and P. Sazanoff, that it absorbs nitric oxide; K. A. Hofmann and G. Bugge, that it precipitates ferrous cyanide when treated with hydrocyanic acid; and with ethyl carbylamine, it gives crystals of a ferric salt, $\text{Fe}_2\text{Cl}_4\text{O} \cdot 5\text{C}_3\text{H}_5\text{N}$; and L. Levi-Bianchini observed that the chloride is decomposed at the critical temp. of the soln. C. F. Wenzel, M. Hamers, and F. Jahn observed that anhydrous ferrous chloride is soluble in conc. **ethyl alcohol**. R. Boyle noted that the tetrahydrate is soluble in alcohol. T. Graham noted that the anhydrous chloride adsorbs the vapour of ethyl alcohol as well as steam. G. Pellini and D. Meneghini observed that the yellowish-green soln. becomes paler when it is cooled. When the soln. is exposed to sunlight, L. E. Jonas said that ferric hydroxide is precipitated. C. Cattaneo found that the sp. electrical conductivities referred to mercury at 0° , of soln. with 0.0823, 0.0088, and 0.00087 eq. of the salt per litre, at 18° , are 27.4×10^9 , 5.67×10^9 , and 1.02×10^9 respectively, and the temp. coeff. 0.014, 0.012, and 0.015 respectively. The sp. conductivity of the alcohol alone was 0.221×10^9 at 18° . M. Faraday found that the soln. is paramagnetic; C. Matteucci examined the magnetic properties of non-homogeneous mixtures of the soln. with olive oil. G. Pellini and D. Meneghini said that when hydrogen is passed through the soln. it remains clear, but with oxygen it becomes turbid. The oxidation of the soln. by air was studied by K. A. Hofmann and G. Bugge, P. Nicolardot, and A. G. Doroschewsky and A. J. Bardt. According to V. Thomas, the evaporation of the soln. furnishes crystals of ferrous chloride associated with alcohol of crystallization. K. Seubert and A. Dorrer found that with an alcoholic soln. of iodide, a deep brown liquid is formed containing FeCl_2I . F. Huttner, and W. Manchot and F. Huttner observed that the soln. absorbs nitric oxide. W. Manchot and J. Haas observed that neither carbon monoxide nor ethylene unites with the salt in alcoholic soln. F. Saenger observed that an alcoholic soln. of sodium alcoholate forms a black substance with anhydrous ferrous chloride—possibly ferrous alcoholate.

F. Jahn said that ferrous chloride is insoluble in **ether**; and H. E. Williams, that the tetrahydrate is only sparingly soluble in ether. A. F. Gehlen obtained a

precipitate of a ferrous salt when the ethereal soln. is exposed to light. C. Cattaneo gave 0.00125 for the sp. electrical conductivity of 0.0011N- FeCl_2 at 18° , and -0.020 for the temp. coeff. V. Thomas obtained red, prismatic crystals when the ethereal soln. is evaporated. W. Manchot and J. Haas could not prepare a compound of ether and ferrous chloride directly, but by warming an ethereal soln. of ferric chloride, best with the addition of phosphorus at 140° to 150° , a complex salt was formed, and it is probably the complex which J. Kachler reported as ferrous ethylenechloride. V. Thomas noted the absorption of nitric oxide by the ethereal soln. K. A. Hofmann and G. Bugge obtained analogous results with ethyl carbylamine to those obtained with the soln. in methyl alcohol. When the aq. soln. of ferrous chloride is treated with ether, F. Jahn observed that the ethereal layer is almost free from iron. H. Wieland and F. Chrometzka studied the catalytic decomposition of **ethyl peroxide** by ferrous salts. W. Eidmann, W. H. Krug and K. P. McElroy, P. Schulz, and A. Naumann and P. Schulz found that ferrous chloride is soluble in **acetone** forming a yellow soln. A brown precipitate is simultaneously formed—probably a ferric oxychloride. P. Schulz said that acetone oxidizes a soln. of ferrous chloride to ferric chloride. F. Huttner, and W. Manchot and F. Huttner observed that the acetone soln. absorbs nitric oxide. V. Thomas observed that ferrous chloride is slightly soluble in glacial **acetic acid**, and the soln. absorbs nitric oxide. J. Rill, and A. Naumann and J. Rill found that ferrous chloride is sparingly soluble in **methyl acetate**. S. Hakomori studied the action of **oxalic, citric, malic, and succinic acids**. E. Linckh, F. Huttner, W. Manchot and F. Huttner, E. Alexander, and A. Naumann and E. Alexander observed that the soln. in **ethyl acetate** is $0.04M$, and it absorbs nitric oxide; E. Linckh, and F. Huttner and E. Linckh, that the soln. in **ethyl malonate** is $0.01M$, and it absorbs nitric oxide; F. Huttner, and W. Manchot and F. Huttner, that the soln. in **ethyl benzoate** is $0.0667M$, and it absorbs nitric oxide; and W. Eidmann observed that the salt is insoluble in **methylal**. V. Thomas found that, in the cold, **phenol** does not dissolve ferrous chloride, and when heated, there is a reaction with the evolution of heat and the formation of a black product. B. Köhnlein observed no reaction with **propyl chloride**. E. Shpolsky examined the retarding effect of ferrous chloride on the photochemical decompositions of Eder's soln.

A. Schier, and A. Naumann and A. Schier found that ferrous chloride readily dissolves in **acetonitrile** forming a colourless soln.; and A. Naumann, and J. Kämmerer, that it forms a yellow soln. with **benzonitrile**. W. Hieber and co-workers, and R. E. Breuil prepared a complex with **ethylenediamine**, $[\text{Fe en}_3]\text{Cl}_2$. J. C. Duff and E. J. Bills observed that with **hexamethylenetetramine**, pale green, microcrystalline plates of **ferrous hexamethylenetetraminochloride**, $\text{FeCl}_2 \cdot 2\text{C}_6\text{H}_{12}\text{N}_4 \cdot 9\text{H}_2\text{O}$, are formed. According to J. Schröder, and A. Naumann and J. Schröder, when anhydrous ferrous chloride is treated with **pyridine**, a part forms a greenish-yellow soln., and a part forms a complex ferrous pyridinochloride. F. Reitzenstein found a feebly acidified soln. of ferrous chloride gives a dark green colour with an excess of pyridine. A. Werner and W. Schmujloff measured the raising of the b.p. of pyridine by the ferrous salt, but J. Schröder showed that the b.p. is lowered, not raised. E. Linckh said that the most conc. soln. is $0.1M$. N. Costachescu and G. Spacu observed that the soln. becomes reddened by oxidation in air. J. Schröder found that a fresh soln. is not changed by water, but an aged soln. deposits ferric hydroxide. Chlorine, bromine, and iodine act as oxidizing agents; soluble chlorides, bromides, and iodides have no action; the halide acids, and sulphur dioxide have no perceptible effect; dry hydrogen sulphide has at first no perceptible action, but traces of ferrous sulphide are precipitated after a prolonged action; ammonia gives a reddish-brown substance which is rapidly darkened on exposure to air; F. Huttner, and E. Linckh found that nitric oxide is absorbed by the soln.; and J. Schröder, that with ammonium thiocyanate, ammonium chloride is precipitated; metals have no action; and silver sulphate precipitates ferrous sulphate. N. Costachescu and

G. Spacu, and R. Weinland and co-workers prepared **ferrous tetrapyridinechloride**, $\text{FeCl}_2 \cdot 4\text{C}_5\text{H}_5\text{N}$, by the action of pyridine on anhydrous ferrous chloride in the cold; and W. Hieber and co-workers, by the action of 4 or more mols of pyridine on a mol of $\text{Fe}(\text{CO})_4\text{Cl}_2$. It is not yet settled whether the co-ordination formula is $[\text{Fe}(\text{C}_5\text{H}_5\text{N})_4\text{Cl}_2]$ or $[\text{Fe}(\text{C}_5\text{H}_5\text{N})_4]\text{Cl}_2$. The canary-yellow, crystalline salt is stable in an atn. of pyridine, but it is slowly oxidized by dry air; it is decomposed by water. W. Hieber and E. Levy studied the heat of formation; and O. Stelling, the X-ray spectrum. R. Weinland and co-workers found that when the complex is treated with methyl or ethyl alcohol, it loses 2 mols. of pyridine forming **ferrous dipyridinechloride**, $\text{FeCl}_2 \cdot 2\text{C}_5\text{H}_5\text{N}$; and W. Hieber and G. Bader obtained the same product by the action of 2 mols of pyridine on one mol of $\text{Fe}(\text{CO})_4\text{Cl}_2$. F. Reitzenstein, and P. Pfeiffer reported $\text{FeCl}_2 \cdot 3\text{C}_5\text{H}_5\text{N} \cdot \text{H}_2\text{O}$, which N. Costachescu and G. Spacu consider to be the impure tetrapyridinechloride. W. Hieber and E. Levy studied the heat of formation, and O. Stelling the X-ray spectrum. F. L. Hahn and H. Wolf reported a compound with α -**acetaminopyridine**, namely **ferrous α -acetaminopyridinechloride**, $[\text{Fe}(\text{C}_7\text{H}_8\text{N}_2\text{O})_2]\text{Cl}_2$; J. L. C. Schröder van der Kolk, and A. R. Leeds, a complex with **aniline**, namely **ferrous dianilinechloride**, $\text{FeCl}_2 \cdot 2\text{C}_6\text{H}_5\text{NH}_2$; F. Blau, and T. M. Lowry, a complex with α , α' -**dipyridyl**, namely **ferrous α , α' -dipyridylchloride**, $[\text{Fe}(\text{C}_{10}\text{H}_8\text{N}_2)_2]\text{Cl}_2$; and F. Blau, a compound with α -**phenantrolin**, namely **ferrous α -phenantrolinchloride**, $[\text{Fe}(\text{C}_{12}\text{H}_8\text{N}_2)_3]\text{Cl}_2 \cdot n\text{H}_2\text{O}$. K. Kimura and H. Sueda prepared a complex with **dimethylglyoxime**; P. Pfeiffer and F. Tappermann, compounds with **tridiphenyl-** and **triphenanthrolin**; W. Manchot and H. Gall studied the action of ferrous chloride on **ethylene mercaptan**; K. Lehmstedt, on secondary **nitrosamines**; J. H. Long, on the inversion of **cane sugar**; and E. Borsbach, on **quinoline**. S. Swann found that iron salts inhibit the electrolytic reduction of **benzophenone**. R. Chenevix observed that **tincture of glass** reacts when the soln. of ferrous chloride has been exposed to air for some time. J. Dunin-Borkowsky observed the coagulation of **blood** by soln. of ferrous chloride; and W. Pauli studied the action of the salt on soln. of **albumin**.

G. Gore observed that precipitated and calcined **silica** adsorbs no ferrous chloride from a 10 per cent. aq. soln., although the temp. rises about 0.33° if 6.5 grms. of silica be added to 50 c.c. of the soln. A. Gorgeu observed that when a moist current of hydrogen is passed over silica and molten chloride, ferrous oxide, and an oxy-chloride are the chief products, and a neutral ferrous silicate, Fe_2SiO_4 , fayalite is also formed; **ferrous silicate** and ferrous chloride form a little chlorosilicate; and when ferrous chloride is melted with **clay**, ferrous silicate and aluminate are formed. The Glauber's iron tree observed by J. R. Glauber in 1648, is formed when a crystal of hydrated ferrous chloride is placed in a soln. of **water-glass**. It was studied by G. J. Mulder. C. Friedel and J. Guérin observed no complex is formed when ferrous chloride is treated with **titanium tetrachloride**—cold or warm. For the action of **titanous chloride**, *vide* 7. 41, 12. According to J. Hoffmann, green, iridescent crystals of a complex are formed with ferrous chloride and **boron trichloride**—namely **ferrous boro-chloride**, $3\text{FeCl}_2 \cdot \text{BCl}_3$ —when ferroboration is heated in chlorine.

J. Michajlenko and P. Muschinsky observed that upwards of 40° , **magnesium** powder reacts with tetrahydrated ferrous chloride with the evolution of hydrogen; the reaction was discussed by H. N. Warren. J. A. Poumarède found that with **zinc** vapour, ferrous chloride mixed with a little carbon forms dendritic crystals of iron; and H. N. Warren observed that molten zinc acts on a mixture of sodium and ferrous chlorides in accord with $\text{Zn} + \text{FeCl}_2 = \text{ZnCl}_2 + \text{Fe}$.

M. Canac found that if the surface of **aluminium** is rubbed with a hydrochloric acid soln. of ferrous chloride, it becomes lustrous. J. Brown observed that **iron** is attacked by molten ferrous chloride; and C. F. Schönbein, that iron in contact with a soln. of ferrous chloride rusts more rapidly than it does in contact with water. F. Bergius also noted that at an elevated temp., water attacks iron forming

ferrous oxide more slowly than is the case with a soln. of ferrous chloride.

A. Ferrari and M. Carugati found that molten ferrous chloride attacks **platinum**.

H. Meyer discussed the extraction of **cupric oxide** from roasted ores by an aq. soln. of ferrous chloride. T. S. Hunt represented the reaction: $3\text{CuO} + 2\text{FeCl}_2 = 2\text{CuCl} + \text{CuCl}_2 + \text{Fe}_2\text{O}_3$. The reaction is retarded by the sparing solubility of the cuprous chloride. The solubility of this salt is raised by adding some sodium chloride and warming the mixture. Actually the iron is deposited as hydrated ferric oxide and possibly a basic ferric chloride. If a large excess of cupric oxide be present, some basic cupric chloride is formed. With **cuprous oxide**, hydrated ferric oxide is formed, and there is a partial reduction of the oxide to metal, $3\text{Cu}_2\text{O} + 2\text{FeCl}_2 = 4\text{CuCl} + 2\text{Cu} + \text{Fe}_2\text{O}_3$. If sodium chloride be also present, the cuprous chloride passes into soln. W. Kwasnik represented the reaction with **barium dioxide**: $4\text{FeCl}_2 + 4\text{BaO}_2 + 6\text{H}_2\text{O} = 4\text{Fe}(\text{OH})_3 + 4\text{BaCl}_2 + \text{O}_2$. H. Rose, and A. Mailhe observed that when freshly-prepared, moist **mercuric oxide** is added to a soln. of ferrous chloride, a black powder is formed which then becomes a brown mixture of mercurous chloride and ferric oxychloride—the soln. contains mercuric chloride. If only a small proportion of mercuric oxide is added to the soln., white mercurous chloride is precipitated, and the ferric salt remains in soln. H. Pélabon and M. Delwaulle obtained ferric oxide and mercurous chloride as products of the reaction. C. F. Schönbein observed that when **lead dioxide** is added to the soln. of ferrous chloride, a ferric salt and lead chloride are formed. H. Schulze observed that when ferrous chloride is heated with **molybdenum trioxide**, in a stream of carbon dioxide, the reaction can be represented: $\text{FeCl}_2 + 2\text{MoO}_3 = \text{FeMoO}_4 + \text{MoO}_2\text{Cl}_2$; and similarly with **tungsten trioxide**. C. Zengelis found that ferrous chloride does not reduce hydrochloric acid soln. of **molybdates** even when warmed. A. Geuther and E. Forsberg found that when ferrous chloride is melted with **sodium tungstate**, ferrous tungstate and sodium chloride are formed. According to C. Marchal and J. Wiernik, when freshly precipitated **manganese dioxide** is added to a neutral soln. of ferrous chloride, the iron is oxidized quantitatively to a ferric salt. M. Kuhara observed that whilst a soln. of ferrous chloride or a suspension of ferrous hydroxide in water is not changed by boiling, yet, if air be excluded, **ferrous hydroxide** suspended in a boiling, conc. soln. of ferrous chloride, slowly forms magnetite: $\text{FeCl}_2 + 2\text{Fe}(\text{OH})_2 = \text{Fe}_3\text{O}_4 + 2\text{HCl} + \text{H}_2$; with a 15 per cent. soln. of ferrous chloride, hæmatite is formed. Similar results are obtained if a little alkali, powdered calcite, or siderite be added to a soln. of ferrous chloride, and the mixture boiled. When **ferric oxide** is boiled for 5 hrs. with a 20 per cent. soln. of ferrous chloride, magnetite is formed. M. Curie and J. Saddy found that the luminescence of zinc sulphide is diminished by ferrous chloride. E. Schürmann observed that **lead sulphide** is not attacked by a soln. of ferrous chloride.

I. I. Krasikoff and I. T. Ivanoff discussed the solubility of ferrous chloride in soln. of various **metal chlorides**. The aq. soln. of ferrous chloride was found by E. Petersen to become turbid when treated with **potassium fluoride**. The complex salts with the chlorides of ammonium, lithium, sodium, potassium, rubidium, cæsium, magnesium, and cadmium are discussed below. According to T. S. Hunt, **cuprous chloride** dissolves in a soln. of ferrous chloride, and R. Kremann and F. Noss added that the solubility of the cuprous salt increases with the conc. of the ferrous chloride, and the solubility of ferrous chloride in water is likewise raised by the presence of cuprous chloride. When the conc. soln. is diluted, cuprous chloride is precipitated. A complex salt is considered to be formed though it has not been isolated. R. Rosendahl studied the reaction. D. Roberts and F. G. Soper studied the reduction of **silver nitrate** by ferrous sulphate soln.: $\text{Ag}^+ + \text{Fe}^{++} \rightarrow \text{Fe}^{+++} + \text{Ag}$. Ferrous chloride reduces a soln. of **gold chloride**. P. A. von Bonsdorff noticed the precipitation of a complex salt when soln. of ferrous chloride and **mercuric chloride** are mixed—*vide infra*. J. Lifschitz and S. B. Hooghoudt studied the photochemistry of the reaction. According to C. Winther, a soln. of mercuric

chloride is reduced by ferrous chloride when exposed to light, and mercurous chloride is formed: $\text{HgCl}_2 + \text{FeCl}_2 = \text{FeCl}_3 + \text{HgCl}$. When the conc. of the mercuric chloride is constant and relatively small, the rate is nearly independent of the conc. of the ferrous salt. For a given conc. of the latter, the rate increases at first with the amount of mercuric chloride and then diminishes. The maximum is attained when the two salts are present in equimolar quantities. In the case of soln. containing small quantities of mercuric relatively to ferrous chloride, the sensitiveness increases with the dilution, but this is not the case for soln. containing equimolar quantities. Such soln. do not vary to the same extent when the conc. is changed, and the maximum sensitiveness is shown by soln. containing the two salts in 3*M*-conc. The presence or absence of oxygen is without appreciable influence on the equimolar soln., but oxygen reduces the quantity of mercurous chloride obtained when a large excess of ferrous chloride is present. The most active light rays are those of wavelength less than 265μ . This is shown by comparative experiments in quartz, uvial glass, and ordinary glass vessels. A. Béchamp and C. St. Pierre found that **stannous chloride** is not reduced by a boiling soln. of ferrous chloride, whilst with **stannic chloride**, J. Biron obtained a complex salt—*vide infra*. According to N. Bouman, by the addition of a soln. of stannous chloride, the potential of iron in a soln. of ferrous chloride becomes less negative, so that it is then less electro-negative than tin; consequently, it is no longer in the state to precipitate tin from its soln. At the same time, it is shown that reduced iron will precipitate tin from its soln. if boiled with a slightly acidic soln. of stannous chloride. The subject was discussed by I. M. Kolthoff, and F. G. Soper. A. Béchamp observed that a strongly basic soln. of **ferric chloride** gives a precipitate when treated with ferrous chloride, and the precipitate is dissolved when water is added. A. Béchamp and C. St. Pierre found that a soln. of **platinous chloride** is not reduced by a soln. of ferrous chloride. L. F. Nilson observed the formation of complex salts; and P. A. von Bonsdorff found that a complex chloroplatinate is formed when a soln. of **platinic chloride** and ferrous chloride is evaporated.

H. Meyer found that a cold, neutral soln. of ferrous chloride, in the absence of air, attacks **copper carbonate** with the evolution of carbon dioxide, and the formation of hydrated ferric oxide: $2\text{FeCl}_2 + 3\text{CuCO}_3 = 3\text{CO}_2 + \text{Fe}_2\text{O}_3 + \text{CuCl}_2 + 2\text{CuCl}$, and if a sufficient excess of ferrous chloride is present, the cuprous chloride remains in soln. H. Meyer, and J. A. Buchner found that with **calcium carbonate**, as calcite, no change occurs on standing many days in a soln. of ferrous chloride; but a boiling soln. attacks the crystal superficially; the finely-powdered carbonate is more rapidly attacked. J. Sprenger also studied the reaction. E. M. Walton found that when crystals of tetrahydrated ferrous chloride and enneahydrated **ferric nitrate** are triturated together, the mixture becomes liquid.

Complex salts of ferrous chloride.—J. J. Berzelius and W. Hisinger observed that if iron filings be boiled with a sat. soln. of ammonium chloride in a closed vessel, ammonia and hydrogen are evolved, and a soln. is formed, which, on crystallization furnishes bluish-green crystals of **ammonium ferrous tetrachloride**, or *ammonium tetrachloroferrite*, which, in accord with C. A. Winkler's, and A. Chassevant's analyses, are probably $2\text{NH}_4\text{Cl} \cdot \text{FeCl}_2$, or $(\text{NH}_4)_2\text{FeCl}_4$. A. Vogel, and C. A. Winkler prepared the salt by crystallization from soln. of the component salts. The salt has a sharp, saline, and astringent taste; the transparent, octahedral crystals neither deliquesce nor effloresce in air; they give off ammonium chloride when heated, and are easily soluble in water, but not in alcohol when heated. The boiling soln. is reduced by zinc depositing metallic iron. A. Johnsen could not prepare the ammonium salt, although he once obtained $\text{NH}_4\text{Cl} \cdot \text{FeCl}_2 \cdot 6\text{H}_2\text{O}$, but he could not repeat his results. The formation of solid soln. of ammonium and ferrous chlorides was discussed by J. H. van't Hoff. F. W. J. Clendinnen studied the ternary system: $\text{NH}_4\text{Cl}-\text{FeCl}_2-\text{H}_2\text{O}$ at 70° . That temp. was selected so as to eliminate hydrates higher than the dihydrate, but the tetrahydrate does appear at this temp. although it affects only a small portion of the equilibrium diagram,

Fig. 562. A continuous series of solid soln. is formed at the ammonium chloride end, but there is a gap near the ferrous chloride end of the system. For **ferrous hydrazinochloride**, $\text{FeCl}_2 \cdot 2\text{N}_2\text{H}_4$, *vide supra*. A. Chassevant prepared **lithium ferrous trichloride**, or *lithium trichloroferrite*, $\text{LiCl} \cdot \text{FeCl}_2 \cdot 3\text{H}_2\text{O}$, in transparent, green needles by evaporating a soln. of the component salts. In his study of the crystallization of mixed soln. of ferrous and potassium chlorides, H. E. Boeke observed that at 38.3° , **potassium ferrous trichloride**, or *potassium trichloroferrite*, $\text{KFeCl}_3 \cdot 2\text{H}_2\text{O}$, separates out; below this temp. potassium chloride and tetrahydrated ferrous chloride are deposited. H. E. Boeke did not succeed in preparing the **potassium ferrous tetrachloride**, or *potassium tetrachloroferrite*, $\text{K}_2\text{FeCl}_4 \cdot 2\text{H}_2\text{O}$, obtained by J. Schabus in bluish-green monoclinic crystals, by crystallization from a boiling soln. of three parts of potassium chloride, and four parts of ferrous chloride. The salt was prepared by A. Chassevant. A. Johnsen found that the monoclinic crystals have the axial ratios $a : b : c = 1.0348 : 1 : 0.7066$, and $\beta = 89^\circ 40'$. The optical axial angle $2H = 88^\circ 3'$; the sp. gr. is 1.46; the index of refraction for Na-light is 1.4694, and for Li-light, 1.4721. The aq. soln. becomes turbid at 105° . H. E. Boeke found that the *dihydrate* is formed from a soln. of the component salts at 38.3° , and it is stable up to 85° . J. Fritzsche reported that it can be converted into the *monohydrate*; and A. Chassevant obtained the anhydrous salt. C. Ochsenius

FIG. 562.—Equilibrium Diagram for the System: $\text{NH}_4\text{Cl}-\text{FeCl}_2-\text{H}_2\text{O}$ at 70° .

FIG. 563.—Ternary System: $\text{FeCl}_2-\text{KCl}-\text{NaCl}$ at 38.0° .

and H. Precht reported this salt to be associated with the carnallite in the Douglasshall salt-mine at Stassfurt, and the mineral was called **douglasite**. The crystals are monoclinic, and their sp. gr. is 2.162. E. Wilke-Dörfurt and G. Heyne prepared **rubidium ferrous trichloride**, or *rubidium trichloroferrite*, $\text{RbFeCl}_3 \cdot 2\text{H}_2\text{O}$, in pale green, efflorescent crystals of sp. gr. 2.711 at 20° ; **rubidium ferrous tetrachloride**, or *rubidium tetrachloroferrite*, $\text{Rb}_2\text{FeCl}_4 \cdot 2\text{H}_2\text{O}$, in clear, monoclinic crystals of sp. gr. 2.850 at 23° , which effloresce and oxidize in air; **caesium ferrous trichloride**, or *caesium trichloroferrite*, $\text{CsFeCl}_3 \cdot 2\text{H}_2\text{O}$, in green, efflorescent crystals of sp. gr. 2.907 at 17° ; and **caesium ferrous tetrachloride**, or *caesium tetrachloroferrite*, $\text{Cs}_2\text{FeCl}_4 \cdot 2\text{H}_2\text{O}$, in colourless, efflorescent, monoclinic crystals of sp. gr. 3.275 at 20° . E. H. Ducloux discussed the micro-appearance of the double salt. No **sodium ferrous chloride** has been prepared, but, according to H. E. Boeke, **sodium tripotassium ferrous hexachloride**, $3\text{KCl} \cdot \text{NaCl} \cdot \text{FeCl}_2$, occurs in the salt-beds at Nordhausen, Saxony, in association with the carnallite and sylvite. The mineral was called **rinneite**—after F. Rinne. H. Jung gave the formula $[\text{FeCl}_6]\text{K}_3\text{Na}$. According to H. E. Boeke, rinneite occurs in coarsely granular masses of hexagonal crystals, with the cleavage, parallel to the prism, perfect. The crystals are colourless when fresh, but on exposure become green, rose, violet, yellow, and brown. The optical character is positive, and the birefringence is weak. C. W. Cheng gave for the axial ratios of the trigonal crystals $a : c = 1 : 0.574$. The corrosion figures correspond with the ditrigonal scalenohedral symmetry. The pyroelectricity is negative. The dimensions of the elementary rhombohedron

are $a=8.40$ A., and $\alpha=92^\circ 25'$. The sp. gr. is 2.34, and the hardness 3. The salt oxidizes in air but is stable under petroleum. The hot, sat. aq. soln. deposits crystals of potassium chloride on cooling. H. E. Boeke found that a soln. containing the component salts in the molar proportions of rinneite, furnish that salt at 26.4° —*vide* Fig. 563. For the artificial preparation of the triple salt, a soln., obtained by dissolving 5.96 grams of sodium chloride, 20.9 grams of potassium chloride, and 123.4 grams of ferrous chloride ($\text{FeCl}_2 \cdot 4\text{H}_2\text{O}$) in 55.4 grams of water, should be isothermally evaporated at 38° with the addition of a crystal of rinneite. According to R. Kremann and F. Noss, no **cuprous ferrous chloride** has been obtained, but, at 21.5° , the solubility of cuprous chloride is increased by the addition of ferrous chloride, as also that of ferrous chloride by the addition of cuprous chloride, the solid phases in equilibrium with the soln. being respectively cuprous chloride and ferrous chloride. The soln. sat. with respect to both the salts contains 73.20 grms. of ferrous chloride (anhydrous) and 23.20 grms. of cuprous chloride in 100 grms. of water.

A. Ferrari and A. Inganni found that with **calcium and ferrous chlorides** there is a eutectic at 592° , with 44.5 mol. per cent. of CaCl_2 , Fig. 564. The results for **strontium and ferrous chlorides**, indicated in Fig. 565, show no miscibility in the solid state, and there is a eutectic at 541° and 50 mol. per cent. of ferrous chloride

FIG. 564.—Freezing-point Curves of Ferrous and Calcium chlorides.

FIG. 565.—Freezing-point Curves of Ferrous and Strontium chlorides.

H. E. Boeke studied the binary system with soln. of ferrous and magnesium chlorides, and the ternary system with soln. of potassium, magnesium, and ferrous chlorides. Tetrahydrated ferrous chloride, in contact with the sat. soln., forms the dihydrate at 72.6° , but in a sat. soln. of magnesium ferrous chloride, the dihydrate forms at 43.2° . Triclinic crystals of **magnesium ferrous tetrachloride**, or *magnesium tetrachloroferrite*, $\text{MgFeCl}_4 \cdot 8\text{H}_2\text{O}$, separate at 22.8° . The equilibrium conditions are illustrated by Figs. 566, 567, and 568. The common occurrence of ferric oxide in carnallite, which makes the colour of this mineral red, is generally explained by assuming that the oxide has been formed by the oxidation of ferrous chloride. H. Precht assumed that the oxidation was effected by the water of crystallization of carnallite and that hydrogen escaped; E. Erdmann could not find evidence in favour of such a reaction, and assumed that the oxidation was due to the mixture of hydrogen and oxygen formed by the action of radium emanation. A. Johnsen showed that the orientation of the plates of iron-mica in primary carnallite support H. Precht's assumption. Carnallite was shown by H. E. Boeke to have a small tendency to form isomorphous mixtures with ferrous chloride, and that ferric chloride has no such tendency. A. Ferrari and M. Carugati found that the crystal lattices of the system $\text{FeCl}_2\text{--MgCl}_2\text{--H}_2\text{O}$.

FIG. 566.—Equilibrium in the System: $\text{FeCl}_2\text{--MgCl}_2\text{--H}_2\text{O}$.

showed that a complete series of solid soln. is formed. The m.p. curve is shown in Fig. 566. A. Ferrari and A. Inganni observed no miscibility in the system

FIG. 567.—Equilibrium in the System : $\text{FeCl}_2\text{-MgCl}_2\text{-KCl-H}_2\text{O}$ at 22.8° .

FIG. 568.—Equilibrium in the System : $\text{FeCl}_2\text{-MgCl}_2\text{-KCl-H}_2\text{O}$ at 43.2° .

FIG. 569.—Freezing-point Curves of the System : $\text{MgCl}_2\text{-FeCl}_2$.

FIG. 570.—Freezing-point Curves of the System : $\text{ZnCl}_2\text{-FeCl}_2$.

FIG. 571.—Freezing-point Curves of the System : $\text{CdCl}_2\text{-FeCl}_2$.

FIG. 573.—The System : $\text{PbCl}_2\text{-FeCl}_2$.

with **zinc and ferrous chlorides**, and the eutectic temp. is the same as the m.p. of zinc chloride, namely, 300° . C. von Hauer obtained colourless, non-efflorescent

crystals of **cadmium ferrous hexachloride**, $2\text{CdCl}_2 \cdot \text{FeCl}_2 \cdot 12\text{H}_2\text{O}$. A. Ferrari and M. Carugati found that the crystal lattices of the system FeCl_2 - CdCl_2 show that a complete series of solid soln. is formed. The m.p. curve is shown in Fig. 571. P. A. von Bonsdorff prepared honey-yellow, deliquescent, rhombic prisms of **mercuric ferrous tetrachloride**, $\text{HgCl}_2 \cdot \text{FeCl}_2 \cdot 4\text{H}_2\text{O}$ —*vide supra*. E. Harbort described rhombohedral crystals of a hydrated **ferrous aluminium oxychloride**, $9\{(\text{Fe}, \text{Mg}, \text{Ca})\text{Cl}_2 \cdot 2\text{H}_2\text{O}\} \cdot 2(\text{Al}_2\text{O}_3 \cdot \text{H}_2\text{O})$, occurring in the German potash deposits. It was called **zirklerite**—after Bergrat Zirkler. E. von Biron prepared **stannic ferrous hexachloride**, $\text{SnFeCl}_6 \cdot 6\text{H}_2\text{O}$ —*vide* 7. 46, 17. A. Ferrari and C. Colla studied the m.p. of the system: SnCl_2 - FeCl_2 , and of the **lead-ferrous chloride** system. No compounds were formed. With the former system, Fig. 572, there is a eutectic at 240° , with about 2 mol. per cent. of FeCl_2 ; and in the latter system, Fig. 573, one at 421° with 28.5 mol. per cent. of FeCl_2 —m.p. 675° to 680° . R. F. Weinland and co-workers obtained **ferrous bismuth chloride**, $\text{FeCl}_2 \cdot 4\text{BiCl}_3 \cdot 12\text{H}_2\text{O}$, by the action of bismuth chloride on a hydrochloric acid soln. of ferrous chloride. A. Ferrari and co-workers examined isomorphous mixtures of **ferrous and manganous chlorides**, and found the X-radiograms agreed with $\text{FeCl}_2 \cdot \text{MnCl}_2 = 8:2$, $a = 7.16 \text{ \AA}$, $a:c = 1:2.434$; for $6:4$, $a = 7.17 \text{ \AA}$, and $a:c = 1:2.419$; for $4:6$, $a = 7.18 \text{ \AA}$, and $a:c = 1:2.404$; for $2:8$, $a = 7.19 \text{ \AA}$, and $a:c = 1:2.387$. The m.p. of mixtures of manganous and ferrous chlorides, plotted in Fig. 574, are:

FeCl_2	0	20	40	60	80	100 per cent.
M.p.	650°	652°	656°	661°	668°	674°

§ 37. The Iron Chlorides—Ferric and Ferrous Chlorides

The history of ferric chloride is indicated in the previous section. In 1819, J. F. L. Hausmann¹ noticed a brownish-red incrustation on the lavas of Vesuvius, and A. Scacchi observed in recent eruptions a yellow or brownish-red incrustation associated with the lavas of fumaroles or steam holes. The coloration was attributed to the presence of **ferric chloride**, FeCl_3 , and A. Scacchi called the mineral *molysite*, which J. D. Dana altered to **molysite**—from $\mu\acute{o}\lambda\omega\iota\varsigma$, a stain—in allusion to its staining the lavas. Drops of ferric chloride often exude from the surface of meteoric irons; A. Daubree called the drops *stigmatite*; they are formed by the oxidation of lawrencite (*q.v.*).

The formation and preparation of ferric chloride.—As pointed out by H. Davy,² J. Davy, J. J. Berzelius, R. Phillips, J. L. Gay Lussac, I. E. Adaduroff, M. Goble, F. Wöhler, A. W. F. Rogstad, etc., when a piece of red-hot iron is introduced into chlorine gas, the iron burns with a red glow forming ferric chloride. H. Davy said that the chloride which is formed volatilizes “at a moderate heat, filling the vessel with beautiful, minute crystals of extraordinary splendour and collecting in brilliant plates.” The same result occurs when a rapid current of dry chlorine is passed over iron wire, cut into short pieces, say, 6 mm., and gently heated in a retort. The ferric chloride volatilizes, and condenses in reddish crystals in the cooler part of the tube. The chlorine gas can then be displaced by a current of dry carbon dioxide, and the salt transferred to a tube, and hermetically sealed. Several books for the laboratory give detailed directions for the preparation of the salt—*e.g.*, those of H. and W. Biltz, L. Vanino, etc. The process was described by H. Wolfram, W. Hampe, F. W. Bergstrom, A. S. Miller, W. Grünwald and V. Meyer, and O. Hönigsmid and co-workers. H. C. Jones and C. F. Lindsay recommended using iron filings washed with alcohol and ether to remove fats; C. G. Maier recommended using electrolytic iron heated between 400° to 500°, and subliming the product three times in an atm. of chlorine at 300°. Sublimation in vacuo results in the dissociation of some of the ferric chloride to form ferrous chloride. B. H. Jacobson recommended treating iron with liquid bromine, and then decomposing the ferric bromide with chlorine. These reactions occur at a comparatively low temp.

A. Vosmaer found that ferrochromium or ferrotungsten, and J. Meyer and R. Backa that ferrovanadium, furnish ferric chloride when heated in chlorine gas—a chloride of the

second element is also formed. Ferric chloride was also produced by P. Nicolardot when liquid sulphur monochloride acts on iron; K. Ott, and H. B. North and A. M. Hageman obtained a similar result by the action of thionyl chloride at 150°; H. B. North, by the action of sulphuryl chloride; W. L. Ray, by the action of selenium oxydichloride; E. Baudrimont, and H. Goldschmidt, by the action of phosphorus pentachloride; and L. Hackspill and L. Grandadam, by the action of alkali chlorides at 800°.

J. L. Gay Lussac, E. Mitscherlich, and H. St. C. Deville obtained ferric chloride by passing a rapid current of dry hydrogen chloride over red-hot precipitated ferric oxide; with a slow current of gas, crystals of ferric oxide are formed by the action of the steam produced in the reaction: $\text{Fe}_2\text{O}_3 + 6\text{HCl} \rightleftharpoons 3\text{H}_2\text{O} + 2\text{FeCl}_3$. J. B. Moyer recommended using a temp. of 200°, and said that ferric chloride quickly volatilizes, leaving behind some less volatile ferrous chloride. F. A. Gooch and F. S. Havens observed that at 180° to 200°, about 5 to 10 per cent. of the oxide is converted into ferrous chloride; and at 500°, all the iron oxide is converted into ferric chloride. If a little chlorine is associated with the hydrogen chloride, all the ferric oxide is transformed to ferric chloride at 180° to 200°. The hydrogen chloride process, or a mixture of hydrogen and chlorine was employed on roasted iron ores by E. Diepschlag, A. and P. Buisine, the Vereinigte Stahlwerke, and F. Bullnheimer. R. Weber, and H. Schulze said that roasted iron ores, containing ferrous and ferric oxides, furnish ferric chloride when heated to redness in chlorine gas, M. Berthelot observed that the reaction between chlorine and ferrous oxide is exothermal, and with ferric oxide endothermal, but W. Kangro and R. Flügge added that at 700° to 800°, the reaction with ferric oxide and chlorine is exothermal. The reaction with precipitated oxide roasted at 1000° is perceptible at 600° and proceeds more quickly as the temp. is raised; at 1000°, magnetite, hæmatite, and minette ore are converted quantitatively into ferric chloride; and at 900°, oolitic earth, and ores of the xanthosiderite type. The Vereinigte Stahlwerke observed that by increasing the press. of the gas, the speed of the reaction is raised. E. Kothny observed the formation of ferric chloride in the chloridizing roasting of pyrites. H. Quantin, and F. P. Venable and D. H. Jackson found that ferric oxide is readily converted into ferric chloride by heating it to about 460° in a mixture of carbon monoxide and chlorine; the Badische Anilin- und Sodafabrik treated chromite, and E. W. Wescott, and H. Bergius treated roasted iron ores in a similar manner. E. Chauvenet, and W. Heap and E. Newbery converted ferric oxide to ferric chloride by heating it above 350° in a current of carbonyl chloride; and P. Camboulives used carbon tetrachloride above 245°; and R. D. Hall, sulphur monochloride. H. B. North and A. M. Hageman observed the formation of ferric chloride when ferric oxide is heated with thionyl chloride; W. L. Ray, with selenium oxydichloride; G. Rauter, with silicon tetrachloride, at 180° to 190°; R. Weber, with phosphorus pentachloride; and H. Bassett and H. S. Taylor, with phosphoryl chloride. H. Arctowsky found that ferric chloride is formed by passing the vapour of ammonium chloride over ferric oxide above 350°. The Vereinigte Stahlwerke used the same process with oxidized ores; H. Bergius heated the oxidized ore with carbon and sodium chloride; and K. A. Hofmann and K. Hörschele heated ferric oxide with molten magnesium chloride and obtained a sublimate of ferric chloride.

J. Davy observed that when ferrous chloride is heated in chlorine, it is quantitatively converted into ferric chloride; and the formation of ferric chloride by heating ferrous chloride in air has been previously discussed. D. Tyrer used a process based on this reaction. H. Rose observed that when chlorine is passed over heated iron sulphide, ferric chloride and sulphur monochloride are formed; and W. Kangro and R. Flügge found that the reaction with pyrite is rapid and complete at about 900°. The process was studied by R. Brandt, T. R. Forland, and E. W. Wescott. E. Chauvenet observed that pyrites forms ferric chloride when heated with carbonyl chloride at 350°, and E. F. Smith obtained a similar result with arsenopyrite, pyrite, and marcasite and liquid sulphur monochloride; H. B. North and C. B. Conover, with thionyl chloride in a sealed tube at 150°;

A. P. Brown, with ammonium chloride at 335° ; and H. Vater, with fused sodium chloride. C. Hensgen converted anhydrous ferrous sulphate into ferric chloride by heating it in a current of hydrogen chloride. A. Conduché obtained ferrous and ferric chlorides by the action of heated chloroform on ferrous or ferric sulphates. K. H. Oenicke observed no ferric chloride was formed from a mixture of sodium chloride and ferrous sulphate at a temp. at which sublimation occurs, but at a higher temp. ferric chloride is produced. A. Baur, and H. St. C. Deville and L. Troost prepared ferric chloride as a sublimate by heating a mixture of equal parts of dehydrated ferrous sulphate and calcium chloride. G. J. Fowler observed that iron nitride inflames spontaneously in chlorine forming ferric chloride and nitrogen; P. Jannasch and F. Schmidt, that ferric nitrate heated in hydrogen chloride at 110° to 120° forms a mixture of ferrous and ferric chlorides. W. Kangro and R. Flügge observed that ferrous phosphate at 900° is converted by chlorine into ferric chloride, the phosphorus remains in a non-volatile form. H. Quantin substituted carbon tetrachloride for chlorine, and obtained a quantitative chlorination of the iron. H. Schröder converted aluminium iron phosphates into volatile ferric chloride by heating them with calcium or magnesium chloride, or carnallite. F. Wöhler found that ferrous carbonate is converted by chlorine into ferric chloride, ferric oxide, and some ferrous chloride—W. Kangro and R. Flügge said the conversion can be completed at 900° . C. Friedel and J. Guérin observed that titanium chloride converts red-hot ferrous carbonate into ferric chloride, etc. W. Kangro and R. Flügge observed that chamosite, and iron aluminosilicate, at 900° is converted by chlorine into ferric chloride, etc. H. von Wartenberg noted that the iron in porcelain at 1000° to 1100° is attacked by chlorine; and F. W. Clarke and E. A. Schneider, that at 400° , only a little of the iron in iron-mica is converted into ferric chloride. For roasted silicates, etc., *vide supra*. C. Friedel and J. Guérin observed that chlorine passed over heated ferrous titanate yields ferric chloride quantitatively; and F. Wöhler, that ferrous tungstate under similar conditions yields ferric chloride and tungsten oxychloride.

Anhydrous ferric chloride is formed by the dehydration of the hydrated ferric chlorides. E. C. J. Mohr said that the dehydration does not occur at ordinary temp. over conc. sulphuric acid, but above 50° , the anhydrous salt is formed; and H. W. B. Roozeboom found that in soln. with over 84 per cent. of ferric chloride, the anhydrous salt is the stable form above 66° . A. Béchamp, J. J. Berzelius, J. B. A. Dumas, M. Goble, C. F. Mohr, and E. L. Schubarth heated the crystals of the hydrate very slowly and obtained a sublimate of ferric chloride. According to P. L. Hulin, the poor yields are due to hydrolytic changes and they can be avoided by heating the chloride in chlorine or hydrogen chloride.

The hydrates of ferric chloride.—The red liquid formed by the deliquescence of ferric chloride was formerly called *oleum martis*. C. W. Scheele observed that iron filings in moist chlorine dissolve to form a liquid. According to J. J. Berzelius, L. J. Thénard, C. F. Bucholz, M. Goble, B. Sandrock, P. J. Béal, A. and P. Buisine, and M. J. B. Orfila, an aq. soln. of ferric chloride is readily formed by dissolving ferric oxide, or hydrated ferric oxide, in hydrochloric acid; C. F. Mohr, F. Leteur, J. Fritzsche, and E. Soubeiran used powdered hæmatite. F. W. J. Clendinnen observed that the conc. soln. attacks filter-paper so that it is better to use fine silver gauze for the filtration. Ferric chloride is readily obtained by dissolving iron to saturation in hydrochloric acid, boiling the soln., and then oxidizing it with chlorine or nitric acid. J. E. de Vry, and B. Sandrock, oxidized the soln. of iron in hydrochloric acid by saturating the liquid with chlorine. J. W. Retgers pointed out that the reaction is slow at ordinary temp., and J. W. Retgers, F. W. C. Krecke, G. Krüss and H. Moraht, and F. A. Flückiger recommended warming the liquid to about 50° when it is treated with chlorine. A. Béchamp recommended removing the excess of chlorine by warming the liquid to 50° , and A. A. Noyes, and G. Krüss and H. Moraht, by passing a current of air through the liquid. The oxidation with chlorine on a large scale was recommended by F. Chemnitz, and D. Tyrer. The

oxidation of the soln. of iron in hydrochloric acid by nitric acid was recommended by F. L. Winckler, B. Sandrock, and E. L. Schubarth. F. A. Flückiger represented the reaction: $3\text{FeCl}_2 + 3\text{HCl} + \text{HNO}_3 = 3\text{FeCl}_3 + \text{NO} + 2\text{H}_2\text{O}$. J. E. de Vry pointed out the difficulty of removing the excess of nitric acid; a small excess may be driven off when evaporating the soln., but some nitric acid still contaminates the crystals. E. B. Shuttleworth stated that the oxidation proceeds more rapidly and completely if the soln. of ferrous chloride be added to the nitric acid than conversely—presumably owing to a better admixture.

The preparation of ferric chloride from by-products in the manufacture of other products, or for special purposes, was described by C. A. Burghardt, C. A. Hall, and L. Paul. Commercial preparations of anhydrous and hydrated ferric chloride were examined by M. Popp, J. C. Hostetter and H. S. Roberts, P. Piazza, C. H. Briggs, F. A. Flückiger, K. Feist, G. Romijn, and F. Richard and A. Malmy. The chief impurities observed were iron oxychloride, ferrous chloride, hydrochloric acid, nitrates, nitrites, chlorides, sulphates of copper, manganese, and zinc. R. Peters, H. W. Fischer and E. Brieger, R. Peters, and G. Schult discussed the preparation of clear, colourless, aq. soln. of ferric chloride by dissolving sublimed ferric chloride in water.

P. P. von Weimarn obtained a glassy, transparent, yellow or pale green gelatinous mass by the rapid cooling of a soln. of ferric chloride. Crystals of the **hexahydrate**, $\text{FeCl}_3 \cdot 6\text{H}_2\text{O}$, separate when the conc., aq. soln. of ferric chloride, acidified with hydrochloric acid, is allowed to stand in the cold. J. R. Glauber, and M. H. Klaproth probably obtained crystals of this hydrate in the seventeenth and eighteenth centuries. The crystals were also obtained by C. F. Bucholz, R. Engel, J. Fritzsche, W. Hampe, M. Kinast, C. F. Mohr, H. W. B. Roozeboom, P. Sabatier, G. Schult, C. Stein, and F. L. Winckler. The hexahydrate is obtained by saturating a soln. of ferric chloride with hydrogen chloride, and concentrating the filtered liquid over solid potassium hydroxide in vacuo; or by allowing the conc. soln. to evaporate slowly in the cold. The conditions of equilibrium are indicated in Fig. 575. H. Lescœur concluded from his observations on the dissociation press. of the hydrates that a **tetrahydrate**, $\text{FeCl}_3 \cdot 4\text{H}_2\text{O}$, exists, but this has not been confirmed. According to H. W. B. Roozeboom, crystals of the **hemiheptahydrate**, $\text{FeCl}_3 \cdot 3.5\text{H}_2\text{O}$, are produced from a soln. of the composition $\text{FeCl}_3 + 3.75\text{H}_2\text{O}$, at room temp., by seeding it with a crystal of the same hydrate, pouring off the mother-liquor, melting the crystals, crystallizing the molten mass, and repeating the operations until a product of constant m.p. is formed. The crystals used for seeding can be obtained by melting together crystals of the hexa- and hemipentahydrates so that the composition approximates $\text{FeCl}_3 + 4.12\text{H}_2\text{O}$, solidifying the mass at room temp., and warming it to 27° . The solid which remains consists of crystals of the hemiheptahydrate. The conditions of stability are indicated in Fig. 575. Crystals of the **hemipentahydrate**, $\text{FeCl}_3 \cdot 2.5\text{H}_2\text{O}$, were probably formed by P. L. Geiger, M. Kinast, J. M. Ordway, C. Stein, and G. C. Wittstein, but they thought that they were crystals of the **trihydrate**, $\text{FeCl}_3 \cdot 3\text{H}_2\text{O}$, a hydrate whose existence has not been established. J. Fritzsche first reported the existence of the hemipentahydrate; he obtained it by keeping the hexahydrate over conc. sulphuric acid, when the mixture liquefies, and crystals of the hemiheptahydrate separate out, and finally, the whole mass acquires the same degree

FIG. 575.—The Solubility of Ferric Chloride in Water.

of hydration. The results were confirmed by P. Sabatier, H. Lescœur, and E. C. J. Mohr. H. W. B. Roozeboom added that this hydrate is stable at room temp. over conc. sulphuric acid; and he obtained it by melting the hexahydrate on a water-bath, evaporating off about half the water of hydration, and crystallizing at room temp. The conditions of equilibrium are indicated in Fig. 575. Some hydrogen chloride is lost during the evaporation so that the crystals must be purified by re-melting and re-crystallizing them a number of times. R. Engel obtained this hydrate by passing hydrogen chloride over the hexahydrate for some hours at 100° , and slowly cooling the product. The resulting hemipentahydrate is free from oxychloride. H. W. B. Roozeboom obtained crystals of the **dihydrate**, $\text{FeCl}_3 \cdot 2\text{H}_2\text{O}$, from a soln. of anhydrous ferric chloride in the molten hemipentahydrate at a temp. exceeding 56° . The conditions of equilibrium are illustrated in Fig. 575. The product can be purified by repeatedly crystallizing the molten mass. If the dihydrate is melted in glass vessels, they are nearly always broken when the salt solidifies; and it is preferable to use a mortar for the purification of the salt by fusion and crystallization. H. W. B. Roozeboom and F. A. H. Schreinemakers obtained the dihydrate by passing hydrogen chloride over the hemipentahydrate. H. W. B. Roozeboom obtained the dihydrate by exposing one of the higher hydrates to an atm. where the press. of the water vapour is below 0.1 mm., and it is therefore not formed when the hemipentahydrate is kept over conc. sulphuric acid.

The hydrates of ferric chloride were studied by H. W. B. Roozeboom in the light of the phase rule, and the results are summarized in Fig. 575. The solubilities, *S* grms. of anhydrous chloride per 100 grms. of water, of the different hydrates are as follow:

The *hexahydrate*, $\text{Fe}_2\text{Cl}_6 \cdot 12\text{H}_2\text{O}$, or $\text{FeCl}_3 \cdot 6\text{H}_2\text{O}$,

	-55°	0°	20°	30°	37°	30°	27.4°	20°	8°
<i>S</i> .	49.52	74.39	91.85	106.8	150.0	201.7	219.0	231.1	246.7

The *hemiheptahydrate*, $\text{Fe}_2\text{Cl}_6 \cdot 7\text{H}_2\text{O}$, or $\text{FeCl}_3 \cdot 3\frac{1}{2}\text{H}_2\text{O}$,

	20°	27.4°	32°	32.5°	30°	25°
<i>S</i> .	204.4	218.7	244.0	257.6	272.4	280.0

The *hemipentahydrate*, $\text{Fe}_2\text{Cl}_6 \cdot 5\text{H}_2\text{O}$, or $\text{FeCl}_3 \cdot 2\frac{1}{2}\text{H}_2\text{O}$,

	12°	20°	27°	30°	35°	50°	55°	56°	55°
<i>S</i> .	231.8	251.2	267.5	272.3	281.6	315.2	344.8	360.4	365.9

The *dihydrate*, $\text{Fe}_2\text{Cl}_6 \cdot 4\text{H}_2\text{O}$, or $\text{FeCl}_3 \cdot 2\text{H}_2\text{O}$,

	50°	55°	60°	69°	72.5°	73.5°	72.5°	70°	66°
<i>S</i> .	359.3	365.9	372.8	387.7	420.5	450.2	470.8	502.4	525.9

The anhydrous chloride:

	66°	70°	75°	80°	100°
<i>S</i> .	525.9	529.8	511.4	525.9	535.8

E. Kordes discussed the eutectics of the system. Hydrates reported by J. L. C. Schröder van der Kolk, and J. W. Retgers were shown by E. C. J. Mohr to be solid soln. with ammonium chloride. H. C. Jones and F. H. Getman obtained the percentage solubility, $S=31.66$ at -51° ; H. Mosler, 32.62 at -47.8° ; G. Malquori, 42.66 at 0° ; 49.76 at 25° ; 73.79 at 35° ; and 78.86 at 60° ; E. C. J. Mohr, 49.72 at 25° ; 54.61 at 35° ; Y. Osaka and T. Yaginuma, 49.42 at 25° ; and F. W. J. Clendinnen, 78.42 at 60° . G. Lemoine said that the solubility at 13° corresponds approximately with a 4-molar soln.

According to H. W. B. Roozeboom, the metastable states are represented by dotted lines in Fig. 575. It will be observed that if a line be drawn in the diagram to represent a fixed temp., a little above 30° , it will intersect the solubility curve four times, and the points of intersection represent four different compositions for the sat. soln. at that temp. The eutectic between ice and the hexahydrate is at

—55°. The metastable eutectic between the hexahydrate and the hemipentahydrate is at 15°; the eutectic between the hexahydrate and the hemiheptahydrate is at 27.4°; the eutectic between the hemiheptahydrate and the hemipentahydrate is at 30°; the eutectic between the hemipentahydrate and the dihydrate is at 55°; and that between the dihydrate and the anhydrous salt is at 66°.

The physical properties of ferric chloride.—J. Königsberger and K. K  pferer noted that the colour of the vapour of ferric chloride at 250° is yellowish-brown. C. Friedel and J. M. Crafts also noted the intense colour of the vapour. H. Arctowsky said that molten ferric chloride is a red, mobile liquid. E. F. Smith said that the crystals obtained from soln. in sulphur monochloride are olive-green; and H. B. North and co-workers obtained for soln. in thionyl and sulphuryl chlorides, plates which were garnet-red in transmitted light, and green in reflected light. The crystals of the sublimed salt, said J. Davy, H. Davy, and J. L. Gay Lussac, occur in iron-black, iridescent scales; J. Gobley said that they are dark violet; O. H  nigschmid and co-workers, reddish-brown—in masses almost black; E. Stirnemann, dark green; A. Neuhaus, deep carmine red; H. St. C. Deville, garnet-red in transmitted light and dark green in reflected light; and W. Gr  newald and V. Meyer, purple-red in transmitted light and dark green in reflected light. E. C. J. Mohr found that when obtained by keeping the hydrate over sulphuric acid above 50°, six-sided, reddish-brown plates are formed which in masses appear to be black with a green sheen. H. Arctowsky found that the crystals obtained from molten mixtures are purple-red in transmitted light and dark green in reflected light; and A. E. Nordenskj  ld obtained six-sided plates belonging to the hexagonal or triclinic system with axial ratios approximating $a:c=1:1.235$. E. Stirnemann said that the crystals are trigonal. V. M. Goldschmidt and co-workers, W. Nowacki, and P. Niggli and W. Nowacki discussed the space-lattice of the crystals of the anhydrous salt. H. Hansen showed that the lattice structure of ferric chloride probably consists of individual mol. groups, and that the energy required to break up the lattice is smaller than that required to dissociate the mol. groups. N. Wooster found that the unit rhombohedral cell is $a=6.69$ A., and $c=52^\circ 30'$, or a hexagonal cell with $a=5.92$ A., and $c=1.26$ A. There are two molecules per unit rhombohedral cell, or six molecules per hexagonal cell. The crystals are isomorphous with those of bismuth triiodide.

According to F. A. Fl  ckiger, the crystals of the hexahydrate have a bitter, salty taste if free from hydrochloric acid. The descriptions of the hexahydrate by A. Benrath, R. Engel, F. A. Fl  ckiger, J. Fritzsche, W. Hampe, J. M. Ordway, P. Sabatier, and F. L. Winckler agree that it furnishes reniform masses of lemon-yellow, or pale yellow crystals, or opaque rhombic prisms or plates which, according to H. W. B. Roozeboom, are monoclinic. A. Neuhaus said that in 2 mm. layers, the crystals are pale yellowish-brown and pleochroic—yellow and yellowish-brown. The subject was also discussed by J. W. Retgers, and E. C. J. Mohr. H. W. B. Roozeboom said that the hemiheptahydrate forms monoclinic crystals which are darker in colour than the hexahydrate, and unlike the hexahydrate are dichroic with colours ranging from yellow to blue. A. Neuhaus said that the crystals in 2 mm. layers are dark yellowish-brown, and pleochroic—yellowish-brown to steel-grey. E. C. J. Mohr added that the pleochroism and crystallizing force of this hydrate are not so strong as in the case of the hemipentahydrate. J. L. C. Schr  der van der Kolk said that the double refraction of the crystals of the hemiheptahydrate is positive. R. Engel observed that the crystals of the hemipentahydrate obtained by slow cooling of soln. in hydrochloric acid are garnet-red. A. Neuhaus said that the crystals in 2-mm. layers are dark reddish-brown, and pleochroic—medium to dark reddish-brown. H. W. B. Roozeboom said that the rhombic crystals of the dihydrate are paler red than those of the hemipentahydrate, and that they are pleochroic with a colour ranging from yellow to brown. A. Neuhaus said that the crystals in 2-mm. layers are dark red, and pleochroic—yellowish-red to dark red.

The colour of conc. soln. of ferric chloride ranges from dark yellowish-brown to a reddish-brown; dil. soln. are yellow, and with very dil. soln. the yellow colour may disappear with ageing owing to hydrolysis which results in the formation of colloidal ferric oxide and hydrochloric acid. The colour of the soln. was discussed by C. F. Schönbein; the relation between the colour and conc. of the soln., by F. G. Donnan and H. Bassett, M. G. Mellon, M. Neidle, S. U. Pickering, M. Schneider, and H. M. Vernon; the effect of hydrolysis, and temp., by P. Apéry, F. A. Flückiger, E. J. Houstoun, J. G. MacGregor, E. Schaer, T. Svedberg, and H. M. Vernon; and the use of the soln. as a colour scale in colorimetry, etc., by W. Crookes and co-workers, and H. V. Arny and co-workers. According to K. S. Ritchie, the exposure to sunlight or other sources of intense light of hydrochloric acid soln. of ferric chloride results in an increase in intensity of the colour of the soln.; on removal of the light the soln. slowly return to their initial condition. The fraction of incident light transmitted during a given exposure reaches a maximum near the commencement of the yellow region of the spectrum and falls rapidly to the green. Increased light absorption also results from heating a soln. of ferric chloride. P. P. von Weimarn observed that at liquid air temp., the colour becomes paler yellow or green as the soln. freezes to a glassy mass, conversely, F. A. Flückiger observed that a soln. almost colourless by dilution becomes distinctly yellow when warmed. The colour of conc. soln. is not perceptibly affected by hydrochloric acid, but dil. soln. become yellowish-green; the subject was discussed by H. V. Arny and co-workers, A. Byk and H. Jaffe, F. G. Donnan and H. Bassett, J. C. Hostetter, C. Hüttner, A. Müller, F. Mylius and A. Mazzucchelli, C. R. C. Tichborne, and H. M. Vernon; the effect of sulphuric acid, and alkali sulphates, chlorides of sodium, potassium, ammonium, calcium, and barium, and boric acid, by J. C. Hostetter; sodium and ammonium chlorides, by A. Müller; ammonium, sodium and antimony chlorides, by F. A. Flückiger; calcium and aluminium chlorides, by H. C. Jones and J. A. Anderson; ammonium chloride and potassium bromide, by E. Schaer; and of sulphuric, nitric, and phosphoric acids, and some organic acids and acid phosphates, by V. Macri.

According to H. St. C. Deville and L. Troost, the **vapour density** of ferric chloride is 11.14 at 440°, 11.01 at 619° (air unity). This is in agreement with the **molecular weight** of the salt with the formula Fe_2Cl_6 . C. Friedel and J. M. Crafts, E. Stirnemann, and H. Biltz and F. Meyer showed that between 321.6° and 442.2°, in an atm. of chlorine, the vap. density is virtually constant and is in agreement with the doubled formula Fe_2Cl_6 . Above 500°, the effects of the dissociation $\text{Fe}_2\text{Cl}_6 \rightleftharpoons 2\text{FeCl}_3$ appear. E. Stirnemann found that at 253°, 271°, 285°, and 295°, a litre of the vapour contained respectively 0.3391, 0.9826, 0.302, and 3.43 grms. of Fe_2Cl_6 per litre, corresponding respectively with mol. wts. from 322.4 to 337.0 when the value for Fe_2Cl_6 is 324.4, and for FeCl_3 162.2. For the dissociation: $\text{Fe}_2\text{Cl}_6 \rightleftharpoons \text{Fe}_2\text{Cl}_4 + \text{Cl}_2$, *vide infra*. At high temp. there is also the dissociation: $\text{Fe}_2\text{Cl}_4 \rightleftharpoons 2\text{FeCl}_2$. This explains the low results:

	448°	518°	606°	750°	1050°	1328°
Vapour density . . .	10.487	9.569	8.383	5.458	5.307	5.160

obtained by H. Biltz and V. Meyer, and W. Grünwald and V. Meyer working with an atm. of chlorine. A. Scott obtained a value 136.1 for the mol. wt. in an atm. of nitrogen.

D. I. Mendeléeff found that with soln. of ferric chloride in *water*, the rule that the sp. gr. of equimolar soln. is greater, the higher the mol. wt. of the solute is valid provided the doubled molecule Fe_2Cl_6 is present. R. Peters showed that the lowering of the f.p. of *N*- to 0.0625*N*-soln. of ferric chloride corresponds with mol. wts. falling from 49.4 to 43.7. This indicates that some hydrolysis as well as ionization occurs. In some non-aqueous soln. there is a marked polymerization of the molecule. G. Oddo, G. Oddo and M. Tealdi, and E. Beckmann found that in *phosphoryl chloride* soln. with 0.5307 to 1.8426 grms. of FeCl_3 in 100 grms. of solvent the mol. wt. ranged from 63.67 to 135.07; P. T. Muller, and E. Beckmann

found that the mol. wt. of the salt in boiling *ethyl alcohol* soln. is not far from normal, but there is some evidence of polymerization, thus E. Beckmann found for soln. with 2.37, 6.66, and 11.57 grms. FeCl_3 in 100 grms. of solvent, the respective mol. wts. 195, 176, and 163. The mol. wt. in boiling *ethyl ether* was found by E. Beckmann to vary from 170 to 175 with soln. ranging from 1.53 to 12.70 grms. of FeCl_3 per 100 grms. of solvent. Observations were also made by P. T. Muller, R. Lespieau, and J. Timmermans. The results are near those required for simple molecules, but there is evidence of polymerization; W. E. S. Turner found the mol. association factor to be 1.0 to 1.11. J. Timmermans found that for soln. with 1.228 to 3.125 grms. FeCl_3 per 100 grms. of boiling *acetone*, the mol. wt. fell from 140 to 107.21, and he observed that in conc. soln., an oxychloride is formed; the mol. wt. of 0.589 gm. FeCl_3 in 100 grms. of boiling *chloroform* is 153.9; 0.676 gm. FeCl_3 in 100 grms. of *acetic acid* has a mol. wt. of 82.4; with 1.001 to 1.26 grms. of FeCl_3 in 100 grms. of *sulphonal*, the mol. wt. is 174 to 197.9; with 0.659 to 1.056 grms. FeCl_3 in 100 grms. of *benzophenone*, the mol. wt. ranges from 289.35 to 210.72; and with 0.593 to 2.213 grms. FeCl_3 in 100 grms. of *benzoic acid*, the mol. wt. ranged from 179.9 to 211.86. E. Busch found that with 6.02 to 12.89 grms. of FeCl_3 in 100 grms. of *methylal*, the mol. wt. ranged from 116 to 145; E. Beckmann, that in benzil, the mol. wt. indicates some polymerization; A. Werner and W. Schmujiöff, with 0.38 to 2.07 grms. FeCl_3 in 100 grms. of boiling *pyridine*, the mol. wt. ranged from 146.05 to 150.05; and L. Kahlenberg and A. T. Lincoln, with 1.4792 to 4.7389 grms. of FeCl_3 in 100 grms. of *nitrobenzene*, the mol. wt. ranged from 316.9 to 190.8; and J. Timmermans observed that with nitrobenzene, the mol. wt. decreases with increasing concentration of the soln.

There are no grounds for assuming that the iron in ferric chloride, Fe_2Cl_6 , is quadrivalent, although the mol. wt. of the salt calculated from the vap. density in an atm. of chlorine corresponds with this formula. Writers on the co-ordination theory—R. Weinland, P. Pfeiffer, and A. Werner—regard this polymerized form as a ferric salt of *hexachloroferric acid*, namely:

A. Werner represented the hexahydrate by the formula for *ferric hexaquochloride*, $[\text{Fe}(\text{H}_2\text{O})_6]\text{Cl}_3$; and R. Weinland suggested that by analogy with other hydrates, the colour of the salt rather favours the assumption that the hexahydrate is *ferric chloropentaquochloride*, $[\text{Fe}(\text{H}_2\text{O})_5\text{Cl}]\text{Cl}_2 \cdot \text{H}_2\text{O}$, or else *ferric dichlorotetraquochloride*, $[\text{Fe}(\text{H}_2\text{O})_4\text{Cl}_2]\text{Cl} \cdot 2\text{H}_2\text{O}$. The subject was discussed by R. Reinicke, and H. Hansen.

According to J. P. Grabfield, the **specific gravity** of crystals of anhydrous ferric chloride is 2.804 at $10.8^\circ/4^\circ$; K. Grossmann gave 2.804; and W. Biltz and E. Birk, 2.898 at $25^\circ/4^\circ$. A. Balandin calculated 2.844 for the sp. gr. from the relation between the density, the at. vol. of the components, and the heat of formation of the salt. A. Balandin, I. I. Saslawsky, and H. H. Stephenson discussed the contraction which occurs when the salt is formed from its components; and W. Biltz, and H. W. Fischer, the mol. vol. A. Heydweiller gave for the sp. gr. of soln. with *C* mols of FeCl_3 per litre at $18^\circ/4^\circ$:

<i>C</i>	1	2	3	4	5	6	7	8
Sp. gr.	1.02263	1.04456	1.0870	1.1284	1.1690	1.2090	1.2486	1.3270

Observations on the sp. gr. of aq. soln. have also been made by H. Becquerel, A. Blümcke, F. W. J. Clendinnen, B. Franz, K. Grossmann, H. Hager, H. C. Jones and co-workers, A. Kanitz, G. Lemoine, W. Manchot and co-workers, G. Quincke, and G. Schult. E. Moles and co-workers obtained these results:

FeCl_3 (per cent.)	0.4088	1.6976	8.737	16.199	25.729	43.579	Sat.
Sp. gr. $\begin{cases} 0^\circ & . & 1.0035 & 1.0139 & 1.0774 & 1.1498 & 1.2465 & 1.4705 & — \\ 18^\circ & . & 1.0022 & 1.0121 & 1.0740 & 1.1451 & 1.2411 & 1.4654 & — \\ 25^\circ & . & 1.0003 & 1.0106 & 1.0718 & 1.1428 & 1.2381 & 1.4611 & 1.7934 \\ 35^\circ & . & 0.9976 & 1.0075 & 1.0684 & 1.1390 & 1.2339 & 1.4548 & 1.7849 \end{cases}$							

G. Quincke gave for the sp. gr. of soln. of 11.53, 18.89, 32.94, 48.07, and 54.83 per cent. ferric chloride in methyl alcohol, at 18° to 20°, respectively 0.8928, 0.9638, 1.1335, 1.4177, and 1.5374; A. Blümcke gave for soln. with 5.12, 10.00, 14.30, 12.00, and 32.10 per cent. of ferric chloride the respective sp. gr., at 15° to 19°, 0.836, 0.873, 0.903, 0.963, and 1.063. P. Schulz, and A. Naumann gave 1.1603 for the sp. gr. of a sat. soln. of ferric chloride in acetone at 18°/4°. H. Hager represented the change in the sp. gr. which attends a rise of 1° with soln. between :

FeCl ₃	10 to 19	20 to 29	30 to 39	40 to 44	45 to 49	50 to 60 per cent.
Change	0.0003	0.0004	0.0005	0.0006	0.0007	0.0008

P. F. Gaehr said that the relation between the sp. gr. D , and the concentration C per cent. can be represented by $\log_{10} D = mC$, where m is a constant; D. I. Mendeléeff discussed the relation between the sp. gr. and the mol. wt. of the salt in soln.; A. Taffel, the temp. of maximum density; F. W. C. Krecke, the effect of hydrolysis on the sp. gr.; R. Reinicke, the vol. relations of the water of crystallization; G. Beck, and I. I. Saslawsky, the mol. contraction; and A. Kanitz, and B. Cabrera and E. Moles, the effect of hydrochloric acid on the sp. gr. K. Grossmann found that the contraction δv which occurs when p per cent. of FeCl₂ is dissolved in unit vol. of water is nearly proportional to p so that $\delta v/p$ is approximately constant. He found :

p	1.58	7.14	10.00	17.335	20.00	24.00	32.00 per cent.
δv	0.0034	0.0122	0.017	0.027	0.031	0.038	0.052

The rate of **diffusion** of ferric chloride in aq. soln. was examined by T. Graham, and M. Torre. L. Vanzetti showed that the diffusion of the salt is accompanied by hydrolysis; and I. D. Götz and G. P. Pamfil measured the speed of diffusion of soln. of ferric chloride in water, and in soln. of sodium nitrate. They concluded that the degree of hydration is not affected by the presence of strong electrolytes. The speed of diffusion of the salt in gelatin was examined by R. E. Liesegang, and H. R. Proctor and D. J. Law. T. Redwood found that ferric chloride in aq. soln. readily diffuses through a membrane, and T. Graham, A. Kossel, and P. Nicolardot showed that during the **osmosis** of a soln. of ferric chloride in a dialyzer, hydrolysis occurs, and while hydrochloric acid passes through the membrane, colloidal ferric hydroxide remains. H. G. Byers and C. H. Walter studied the so-called electro-osmosis.

G. Quincke measured the **surface tension** of soln. of ferric chloride and found it to be smaller than that of water. H. Piepenstock represented the lowering of the surface tension of water, in percentages of σ , the value for water alone being such that the lowering $a = 100(\delta\sigma/\sigma)/M$, when $\delta\sigma$ is the difference in the surface tensions of water and of the aq. soln., M denotes the number of eq. FeCl₃ per litre of soln. The concentration of the soln. is expressed in percentages, the temp. approximated 18° :

C	6.83	9.24	12.00	14.56	17.58	22.19	25.40	28.79 per cent.
a	1.92	1.86	1.73	1.71	1.69	1.51	1.43	1.38

The lowering per eq. of ferric chloride in soln. decreases with increasing concentration. The influence of a magnetic field on the surface tension of the soln. was examined by P. Drapier, G. Quincke, and O. Liebknecht and A. P. Wills. W. L. Rolton and R. S. Troop observed that a magnetic field of 16,000 gauss had no perceptible influence on the surface tension of soln. of ferric chloride; L. Abonnenc also obtained a negative result; and D. Owen said that the theoretical change amounts to one in 5×10^6 of the total surface tension by the action of a field of 20,000 gauss. O. Lorant observed that the limiting surface between ethyl ether, chloroform, and nitrobenzene, and an aq. soln. of ferric chloride is greater than is the case with water. G. Quincke made observations on the surface tension and sp. cohesion of soln. in methyl alcohol.

P. de Heen measured the fluidity of soln. of ferric chloride and the results were

discussed by C. Montigny. A. E. Oxley measured the velocity of flow of conc. soln. of ferric chloride at temp. between 0° and 80° . A. Kanitz observed that soln. of ferric chloride have a greater **viscosity** than is usual with soln. of other chlorides. W. Herz calculated from A. Kanitz's measurements of the viscosity, η , of N -, $0.5N$ -, $0.25N$ -, and $0.125N$ - FeCl_3 at 25° , respectively 0.01147, 0.01014, 0.00949, and 0.00922 c.g.s. units. E. Moles and co-workers obtained for soln. with :

FeCl_3 (per cent.)	0.4088	1.6975	8.737	16.199	25.729	43.579	Sat.
$\left\{ \begin{array}{l} 0^{\circ} \\ 18^{\circ} \\ 25^{\circ} \\ 35^{\circ} \end{array} \right.$	$\left\{ \begin{array}{l} 0.018299 \\ 0.010750 \\ 0.009125 \\ 0.007371 \end{array} \right.$	$\left\{ \begin{array}{l} 0.019285 \\ 0.011290 \\ 0.009555 \\ 0.007742 \end{array} \right.$	$\left\{ \begin{array}{l} 0.026489 \\ 0.015380 \\ 0.013040 \\ 0.010358 \end{array} \right.$	$\left\{ \begin{array}{l} 0.039370 \\ 0.022270 \\ 0.018550 \\ 0.014488 \end{array} \right.$	$\left\{ \begin{array}{l} 0.071170 \\ 0.037440 \\ 0.030510 \\ 0.023238 \end{array} \right.$	$\left\{ \begin{array}{l} 0.35208 \\ 0.13770 \\ 0.10515 \\ 0.07202 \end{array} \right.$	$\left\{ \begin{array}{l} - \\ - \\ 0.3164 \\ 0.1942 \end{array} \right.$

A. Smits and co-workers observed that, at 40° , the viscosity increased with the concentration up to 55.4 per cent. FeCl_3 , it then fell to a minimum with 62.5 to 65.0 per cent. FeCl_3 , and thereafter increased rapidly and continuously. The maximum and minimum points correspond very nearly with the hexahydrate and the hemiheptahydrate respectively. The subject was discussed by W. P. Jorissen; and the temp. coeff. of the viscosity by A. E. Oxley. A. Kanitz found that the addition of increasing proportions of hydrochloric acid to the soln. lowers the viscosity, due, it is supposed, to a reduction in the percentage hydrolysis. The effect of hydrolysis on the viscosity was discussed by E. Moles and co-workers, and Wo. Ostwald; and L. Abonnenc found that a magnetic field had no perceptible influence on the viscosity of soln. of ferric chloride.

The **thermal expansion** of soln. can be calculated from the observations of E. Moles and co-workers, and H. Hager on the effect of temp. on the sp. gr. of the aq. soln. O. Hülsmann and W. Biltz made observations on the subject. W. Beetz showed that the **thermal conductivity** of a soln. of sp. gr. 1.126 at 8° to 14° is greater than that of water, and that of a soln. of sp. gr. 1.244 at 8° to 14° is also greater than that of water. The conductivity of dil. soln. between 28° and 36° is smaller than that of water. W. Beetz examined the thermal conductivity of soln. in ethyl alcohol, and ether. A. Blümcke found that the **specific heat** of anhydrous ferric chloride is 0.145 at room temp.; and for 20, 28.8, and 43.56 per cent. aq. soln., respectively 0.813, 0.745, and 0.670. G. Lemoine found the sp. ht. of $3M$ - FeCl_3 , of sp. gr. 1.368, to be 0.66. The subject was studied by N. de Kolossowsky. A. Blümcke examined the sp. ht. of soln. in ethyl alcohol.

A. Brann, and J. H. Walton and A. Brann studied the **rate of crystallization** of aq. soln. of ferric chloride. H. W. B. Roozeboom said that owing to the low temp. of formation of the cryohydrate, -55° , the hexahydrate should make a good freezing mixture with ice, and he obtained -25° by this means. The **lowering of the freezing-point** of water by ferric chloride is indicated by the ice-line in Fig. 575, where H. W. B. Roozeboom found the f.p. of water with 18.01, 34.21, and 42.68 grms. of FeCl_3 per 100 grms. of water to be respectively -10.0° , -27.5° , and -40° , corresponding with the respective mol. lowerings of 9.0° , 13.0° , and 15.2° . H. Mosler found the f.p. of soln. of ferric chloride to be :

FeCl_3	.	.	10.3	23.0	28.5	33.1	38.5	43.4 per cent.
F.p.	.	.	-5.7°	-15.8°	-22.0°	-27.2°	-36.8°	-47.8°

Observations were also made by F. M. Raoult, G. Malfitano and L. Michel, A. A. Noyes, N. Sasaki, and H. C. Jones and co-workers. R. Peters observed for :

FeCl_3	.	.	N -	$0.5N$ -	$0.25N$ -	$0.125N$ -	$0.0625N$ -
F.p.	.	.	2.17°	1.02°	0.51°	0.263°	0.145°
α	.	.	0.82	0.76	0.74	0.80	0.84

The corresponding mol. wts. range from 49.4 to 43.7 showing that the ionization of ferric chloride in aq. soln. can be represented by $\text{FeCl}_3 \rightleftharpoons \text{Fe}^{+++} + 3\text{Cl}^-$. H. C. Jones and F. H. Getman noted that the mol. lowering of the f.p. passes through a

minimum form of concentration between 0.1 and 0.2 molar; thus, representing the concentration in mols per litre, the mol. lowerings of the f.p., Δ , are:

C	0.064	0.103	0.129	0.257	0.515	1.287	1.544	2.573
Δ	6.05	5.89	5.87	6.14	7.16	10.06	11.40	19.82

G. Malfitano, and G. Malfitano and L. Michel discussed the influence of hydrolysis on the results; they observed that the lowering of the f.p., Δ , of a soln. of 5 grms. of FeCl_3 per litre is $\Delta=0.200$; after heating 15 mins. at 115° to 120° , $\Delta=0.300$; and after being kept for a long time at ordinary temp., $\Delta=0.270$. A. A. Noyes found that the lowering of the f.p. of conc. soln. is affected additively by the introduction of hydrochloric acid, but with dil. soln. there is a deviation from the additive law which can be explained by the driving back of the hydrolysis by the acid. The **raising of the boiling-point** of various soln. has been discussed above in connection with the mol. wt. of the salt in soln.

T. Carnelley and W. C. Williams gave 306° to 307° for the **melting-point** of the anhydrous chloride; C. Friedel and J. M. Crafts gave 280° to 285° , and added

FIG. 576.—The Vapour Pressure of Ferric Chloride.

that it volatilizes at the same time; G. Herrmann gave 298° ; E. Stirnemann, 306° ; G. Scarpa, 302° ; and K. Hachmeister, 303° . E. Stirnemann's value, 306° , is at the junction of the sublimation and b.p. curve, Fig. 576. O. Hönigschmid and co-workers observed that if

heated rapidly, the salt can be volatilized without melting; and H. Arctowsky observed that the salt softens at 260° . H. W. B. Roozeboom's values for the m.p. of the hydrates are indicated in Fig. 575. J. M. Ordway gave 35.5° for the m.p. of the hexahydrate; F. A. Flückiger, 38° ; and H. W. B. Roozeboom, 36.5° for the hexahydrate, 32.5° for the hemiheptahydrate, 56° for the hemipentahydrate, and 73.5° for the dihydrate.

The **thermal dissociation** of ferric chloride, $\text{Fe}_2\text{Cl}_6 \rightleftharpoons 2\text{FeCl}_3$, has been discussed in connection with the mol. wt. of the salt. V. and C. Meyer noted that chlorine is evolved by the **thermal decomposition** of ferric chloride at a high temp.: $\text{Fe}_2\text{Cl}_6 = 2\text{FeCl}_2 + \text{Cl}_2$; and W. Grünwald and V. Meyer observed that when ferric chloride is heated in an atm. of nitrogen, the residue contains the less volatile ferrous chloride. Thus, at:

	448°	518°	606°	750°	$>750^\circ$
Decomposition	0	0.100	0.125	0.333	0.3 to 0.5 per cent.

C. Friedel and J. M. Crafts said that the reaction is perceptible in an atm. of nitrogen at 430° ; according to P. Fireman and E. G. Portner, the decomposition, $\text{Fe}_2\text{Cl}_6 \rightleftharpoons \text{Fe}_2\text{Cl}_4 + \text{Cl}_2$, can be detected even at 122° ; and C. G. Maier added that the salt cannot be sublimed in vacuo without some decomposition. E. Stirnemann observed some decomposition of the ferric chloride always occurs when ferric chloride is held at 400° for any length of time; he found the partial press. of the chlorine in the sat. vapour of ferric chloride to be 0.08 to 0.12 atm. at 500° ; 24.1 mm. at 291.5° ; and 31.9 mm. at 301.8° , and this is less than 10 per cent. of the vap. press. of ferric chloride at the corresponding temp.

When the hexahydrate is slowly heated, P. Nicolardot observed that hydrogen chloride and steam, but no chlorine, are evolved; and at 110° the evolution of hydrogen chloride ceases, and there remains ferric oxychloride, FeOCl , which is stable in a dry atm. at temp. up to 250° . At a high temp. the oxychloride decomposes into ferric oxide and chloride and free chlorine. For the action of heat on aq. soln., *vide infra*.

M. H. Klaproth, E. L. Schubarth, F. A. C. Gren, J. Davy, H. Davy, and J. L. Gay Lussac noted the **volatility** of ferric chloride. T. Carnelley and W. C. Williams observed that the salt begins to sublime at 100° ; and C. Friedel and J. M. Crafts, and G. Herrmann, that it volatilizes at its m.p. W. Grünwald and V. Meyer found that the volatilization is slow at 450° , but rapid at 600° . According to K. F. Föhr, W. Skey, D. H. Browne, and A. Vogel, some ferric chloride is lost by volatilization during the evaporation of acidified soln. of the salt; but C. R. Fresenius, L. L. de Koninck, H. P. Talbot, R. W. Atkinson, and H. Seward consider that there is no appreciable loss by evaporation, even at 130° . H. P. Talbot observed a loss of iron when the soln. contains ammonium chloride, or aqua regia. C. Hüttner observed no loss during many hours' evaporation of a soln. on the water-bath, with repeated additions of hydrochloric acid, and a prolonged drying of the residue on the water-bath.

E. Stirnemann gave for the **vapour pressure**, p atm., of anhydrous ferric chloride at:

	253°	271°	285°	301°	310°	370°	403°	493°
p	0.0454	0.131	0.283	0.676	0.855	2.04	3.31	9.1 atm.
	Sublimation curve				Boiling curve			

E. Stirnemann's results are plotted in Fig. 576. The sublimation curve AO , Fig. 576, corresponds with $\log p = 12.442 - 7250T^{-1}$; and the boiling curve OB , Fig. 576, with $\log p = 4.138 - 2544T^{-1}$. The partial press. of the chlorine in the reaction $\text{Fe}_2\text{Cl}_6 \rightleftharpoons 2\text{FeCl}_2 + \text{Cl}_2$ is discussed above; OC represents the fusion curve, or the assumed effect of press. in the m.p. E. Baur studied the system. K. Jellinek and R. Koop gave for the vap. press., p atm., at 200° , 240° , 260° , and 280° , the respective values $p = 0.012$, 0.088 , 0.237 , and 0.508 atm., and C. G. Maier obtained for the dissociation and vap. pressures combined, p mm.:

	216.5°	248.7°	273.4°	285.0°	299.6°	308.8°	313.3°	318.4°
p	3.9	26.6	92.6	162.5	340.9	564.2	729.6	872.6 mm.

W. Kangro and R. Flüge found the partial press., p atm., of ferric chloride, and the equilibrium constant, K , when the press. of the chlorine is 1 atm., to be:

	327°	527°	727°	927°	1127°	1327°
p	0.00044	0.0061	0.030	0.086	1.8	3.3 atm.
K	7.9×10^{-24}	7.9×10^{-16}	5.0×10^{-11}	7.9×10^{-9}	1.6×10^{-5}	1.0×10^{-3}

According to G. Herrmann, the vap. press. of ferric chloride is strongly depressed in the presence of lead and other chlorides; as a result, the mixtures can be heated to a relatively high temp. without the sublimation of the ferric chloride.

H. Lescœur found the vap. press. of a sat. soln. of the hexahydrate is 6.5 mm. at 20° ; and H. W. B. Roozeboom found the vap. press. of a soln. sat. with the hexahydrate at 15° to be 6.0 mm. for BC , Fig. 575, and 1.4 mm. for CN , Fig. 575; for a soln. sat. with the hemiheptahydrate, 2.3 mm. for OD , Fig. 575; for a soln. sat. with the hexahydrate and the hemiheptahydrate, 1.8 mm.; and for a soln. sat. with the hemipentahydrate, 1.3 mm. for MF , Fig. 575—*vide supra*, the preparation of the hydrates. H. Lescœur measured the vap. press. of the different hydrates and found for $\text{Fe}_2\text{Cl}_6.n\text{H}_2\text{O}$, the vap. press. p mm., at about 20° :

n	13.1	12.35	12.0	11.9	8.45	7.45	5.23
p	6.5	5.6	2.8	2.2	2.0	1.2	1.2
	Hexahydrate		Hemihydrate			Hemipentahydrate	

The **boiling-point** of anhydrous ferric chloride was determined by C. Friedel and J. M. Crafts, K. Hachmeister gave 307° for the b.p.; and C. G. Maier computed 315° from the sublimation curve, and E. Stirnemann, 317° . C. G. Maier observed that some decomposition occurs at the b.p. E. Stirnemann calculated the **critical temperature** to be between 650° to 700° , and the **critical pressure**, 45 to 50 atm. E. Stirnemann calculated for the **heat of sublimation**, 33,100 cal. per mol. Fe_2Cl_6 ; for the **heat of vaporization**, 11,300 cal. per mol. Fe_2Cl_6 ; and for the **heat of fusion**, 21,800 cal. per mol. of Fe_2Cl_6 ; K. Jellinek and R. Koop, 24,780 cal. per

mol. Fe_2Cl_6 for the heat of vaporization; W. Kangro and R. Flügge gave 24,000 cal. per mol. Fe_2Cl_6 for the heat of vaporization; and C. G. Maier gave for the heat of vaporization in cal. per mol.:

	256.9°	270.7°	288.2°	301.4°	309.2°	315.0°
Heat of vaporization	29,410	30,590	32,480	34,110	35,090	35,470

T. Andrews obtained a value for the **heat of formation** of ferric chloride which J. Thomsen considered too high, and he calculated from the observations $2\text{Fe} + 2\text{Cl}_2 + \text{Aq.} = 2\text{FeCl}_2 \cdot \text{Aq.} + 199.9$ Cals., and $2\text{FeCl}_2 \cdot \text{Aq.} + \text{Cl}_2 = 2\text{FeCl}_3 \cdot \text{Aq.} + 55.54$ Cals. that $2\text{Fe} + 3\text{Cl}_2 + \text{Aq.} = 2\text{FeCl}_3 \cdot \text{Aq.} + 255.44$ Cals.; and since $2\text{FeCl}_3 + \text{Aq.} = 2\text{FeCl}_3 \cdot \text{Aq.} + 63.36$ Cals., it follows that $2\text{Fe} + 3\text{Cl}_2 = 2\text{FeCl}_3 + 192.08$ Cals., or $\text{Fe} + \frac{3}{2}\text{Cl}_2 = \text{FeCl}_3 + 96.04$ Cals. M. Berthelot gave 96.15 Cals.; W. Biltz and C. Fendius, 96 Cals.; and K. Jellinek and R. Koop, 96.04 Cals. J. Thomsen also gave $(\text{FeCl}_2, \frac{1}{2}\text{Cl}_2, \text{Aq.}) = 27.8$ Cals. J. Thomsen gave $\text{Fe} + \frac{3}{2}\text{Cl}_2 + \text{Aq.} = \text{FeCl}_3 \cdot \text{Aq.} + 127.72$ Cals., a result in good agreement with T. Andrews' value. M. Berthelot gave 127.85 Cals., and observed that the chlorination of iron in the presence of water furnishes 50 Cals. per atom of chlorine for the first two atoms, and 28 Cals. for the third atom of chlorine. J. Thomsen observed that, at 18°, the oxidation of $0.1M\text{-FeCl}_2$ by chlorine furnishes $2\text{FeCl}_2 \cdot \text{Aq.} + 2\text{HCl} \cdot \text{Aq.} + \text{Cl}_2 = 2\text{FeCl}_3 \cdot \text{Aq.} + 2\text{HCl} \cdot \text{Aq.} + 55.48$ Cals., and when hypochlorous acid, or potassium permanganate is used as oxidizing agent, the mean value is 55.542 Cals. M. Berthelot made observations on this subject; with oxygen as the oxidizing agent, $2\text{FeCl}_2 \cdot \text{Aq.} + \frac{1}{2}\text{O}_2 + 2\text{HCl} \cdot \text{Aq.} = 2\text{FeCl}_3 \cdot \text{Aq.} + \text{H}_2\text{O} + 45.269$ Cals. W. Kangro and R. Flügge gave for the reaction $2\text{Fe}_2\text{O}_3 + 6\text{Cl}_2 = 4\text{FeCl}_3 + 3\text{O}_2 - 85$ Cals.; and W. A. Roth and co-workers gave $\text{Fe}_2\text{O}_3 + 3\text{Cl}_2 = 2\text{FeCl}_3 + 30 + 7.4$ Cals. The subject was discussed by E. Rabinowitsch and E. Thilo. J. Thomsen gave $2\text{FeCl}_3 \cdot \text{Aq.} + \text{Fe} = 3\text{FeCl}_2 \cdot \text{Aq.} + 44.41$ Cals.; and T. Andrews, 47.6 Cals. For the **heat of hydration**, P. Sabatier gave $\text{FeCl}_3 + 6\text{H}_2\text{O}_{\text{solid}} = \text{FeCl}_3 \cdot 6\text{H}_2\text{O} + 17.56$ Cals.; and $\text{FeCl}_3 \cdot 2.5\text{H}_2\text{O} + 3.5\text{H}_2\text{O}_{\text{solid}} = \text{FeCl}_3 \cdot 6\text{H}_2\text{O} + 10.36$ Cals. at 20°; $\text{FeCl}_{3\text{solid}} + 2.5\text{H}_2\text{O}_{\text{solid}} = \text{FeCl}_3 \cdot 2.5\text{H}_2\text{O} + 7.2$ Cals.

T. Andrews gave 26.8 Cals. for the **heat of solution** of ferric chloride: $\text{FeCl}_3 + \text{Aq.} = \text{FeCl}_3 \cdot \text{Aq.}$ According to J. Thomsen, this value is too low, and he obtained 31.68 Cals., and for $\text{Fe}_2\text{Cl}_6 + 2000\text{H}_2\text{O}$ he obtained 63.4 Cals. P. Sabatier gave 42 Cals. for the heat of soln. of Fe_2Cl_6 in $24,000\text{H}_2\text{O}$ at 28°; 11.28 Cals. at 20.8° for $\text{Fe}_2\text{Cl}_6 \cdot 12\text{H}_2\text{O}$; and for $\text{FeCl}_3 \cdot 2.5\text{H}_2\text{O}$ in 300 to $600\text{H}_2\text{O}$, 21 Cals. at 20°. W. A. Roth and co-workers gave 12.81 Cals. for the heat of soln. of crystals of ferric chloride at 97°. G. Lemoine obtained for the heat of soln. of a mol of FeCl_3 in n c.c. of water, in about 5000 c.c. of hydrochloric acid, at room temp.:

n	4990	1000	333.3	250
Q	30.97	28.6	23.4	22.6 Cals.

or of a mol of FeCl_3 in about 5000 c.c. of hydrochloric acid, at room temp.:

HCl	0	0.5N-	N-	3N-	6N-
Q	30.97	31.12	29.80	29.23	24.92 Cals.

H. W. B. Roozeboom said that the heat of soln. of the hexahydrate in an aq. soln. of ferric chloride is dependent on the conc. of the ferric chloride. The process of solution is exothermal for dil. soln. with over about 40 mols of H_2O per mol of FeCl_3 , and endothermal for more conc. soln. Similarly with soln. of the hemi-heptahydrate, the process is exothermal for soln. with more than about 6.5 mols of H_2O per mol of FeCl_3 , and endothermal for conc. soln.; and for soln. of the hemipentahydrate the process is exothermal for dil. soln. with over about 5 mols H_2O per mol of FeCl_3 , and endothermal for more conc. soln. G. Lemoine found for the **heat of dilution**, Q Cals. per mol of FeCl_3 in m c.c. of soln., with n c.c. of water, between 12° and 14°:

m	250.0	333.3	1000	2000	3000
n	750.0	666.7	1000	2000	5000
Q	6.0	5.2	1.52	0.98	2.42

The greatest evolution of heat occurred with *M*- and 3*M*-soln.; and no heat was evolved with a 0.25*M*-soln.; but when a 3*M*-soln. is diluted to 0.25*M*-, the heat evolved is 7.7 Cals. greater than the heat of soln. of the hexahydrate, and this is attributed to a change in the state of aggregation of the water of crystallization. When a soln. with 4 gram-atoms of iron per litre is diluted with water, there is a considerable evolution of heat, which is not due to hydration because it is observed when a soln. with $\text{Fe}_2\text{Cl}_6 + 108\text{H}_2\text{O}$ is diluted. Rather is the development of heat due to the gradual hydrolysis of the ferric chloride with the formation of hydrochloric acid, and soluble hydrated ferric oxide. The development of heat is less marked with soln. of other ferric salts. If *M* represents the molar conc. of a soln. of ferric chloride, the percentage changes (hydrolysis) for different dilutions are:

<i>M</i>	4	3	1.5	1.0	0.5	0.25	0.10
Change	100	74	50	46	37	35	29

F. L. Browne and J. H. Mathews found the heat of dilution, *Q* cals. per gram-equivalent of FeCl_3 , of aq. soln. of ferric chloride:

FeCl_3	1.029 <i>N</i> -	0.515 <i>N</i> -	0.257 <i>N</i> -	0.129 <i>N</i> -
<i>Q</i>	190.3	1000.8	31	-38
FeCl_3	0.064 <i>N</i> -	0.032 <i>N</i> -	0.016 <i>N</i> -	0.008 <i>N</i> -
<i>Q</i>	-116	-191	-192	-90

The results are plotted in Fig. 577. There is first a rapid evolution or absorption of heat (depending on the conc. of the soln.) with dilution, and thereafter a slow evolution of heat which occupies many hours. This is taken to mean that the hydrolysis takes place in two stages: the first stage is rapid, the second is a slow reaction. F. L. Browne measured the heat of dilution, *Q* cals. per gram-equivalent of FeCl_3 , and also the hydrolysis in soln. containing the following proportions of ferric chloride, expressed to show the conc. of hydrochloric acid, and of unchanged FeCl_3 . All concentrations are expressed in gram-equivalents per litre:

Total FeCl_3	0.250	0.125	0.0625	0.0313 <i>N</i> -
HCl	0.060	0.035	0.0173	0.0091 <i>N</i> -
Unchanged FeCl_3	0.190	0.090	0.0452	0.0222 <i>N</i> -
<i>Q</i>	31	-89	-172	-212

E. Petersen pointed out that in diluting a rather more than *N*- FeCl_3 , with *N*-HCl, there is an evolution of heat owing to the heat of dilution of the acid; after making an allowance for this, the heat of dilution of the soln. is negative. J. Thomsen measured the **heat of neutralization** of ferric hydroxide with hydrochloric acid, and obtained *Q* cals. per mol of $\text{Fe}(\text{OH})_3$, with:

Mols HCl	1	1.5	2	3
<i>Q</i>	5944	8766	11,504	16,728 cals.

G. Lemoine added that the heat of neutralization is dependent on the concentration and is in accord with the fact that the heat of dilution of conc. soln. of ferric chloride is less than it is with dil. soln. M. Berthelot gave $(\text{Fe}_2\text{O}_3\text{ppd.}, 6\text{HCl.Aq.}) = 33.2$ Cals. P. Nicolardot measured the heat of neutralization of different forms of ferric oxide with hydrochloric acid.

H. Becquerel measured the **index of refraction**, μ , of aq. soln. of ferric chloride and found for the *D*-line and the red *Li*-line, at 15° to 18° except in the case of the 70.6 per cent. soln. where the temp. was 30° to 35°, and the 75 per cent. soln. where the temp. was high enough to prevent the deposition of crystals:

FeCl_3	75	70.6	60	33	16.5	8.25	4.13	2.06
μ_{D-}	1.6163	1.5964	1.5605	1.4382	1.3853	1.3594	1.3466	1.3403
μ_{Li-}	1.6011	1.5823	1.5493	1.4332	—	—	—	—

FIG. 577.—Heats of Dilution of Solutions of Ferric Chloride.

The value for water is 1.3340 with the *D*-line. G. Limann obtained with soln. of concentration *N* equivalents per litre at 18° :

<i>N</i>	0	0.5	1.0	2.0	4.0
μ { <i>Hα</i> -line	1.33139	1.33859	1.34560	1.35903	1.38512
<i>D</i> -line	1.33322	1.34055	1.34769	1.36138	1.38805
<i>Hβ</i> -line	1.33737	1.34502	1.35249	1.36698	—

Observations were also made by A. Hauke, A. Heydweiller, L. R. Ingersoll, H. C. Jones, and H. C. Jones and F. H. Getman. C. E. Richards and R. W. Roberts gave for light of wave-length, λ , at 17° :

λ	6104	5780	5330	5218	5150	4958
μ { 1.045 sp. gr.	1.3470	1.3484	1.3500	1.3508	1.3514	1.3535
1.167 sp. gr.	1.3904	1.3916	1.3940	1.3959	1.3969	—

H. M. Vernon discussed the change of colour which occurs on diluting or raising the temp. of the soln. The **molecular refraction** was measured by J. H. Gladstone who gave for a 27.95 per cent. soln. 50.75 for the *A*-line, and 52.64 for the *D*-line. J. H. Gladstone and W. Hibbert gave for soln. with 11.87 to 27.67 per cent. of FeCl_3 in ethyl acetate the mean mol. refraction 50.36 for the *D*-line. Measurements were also made by A. Hauke. A. Heydweiller gave for soln. of concentration *C*, where *C* represents soln. with 0 to 4.0 gram-equivalents per litre, a mean value of 29.97; and G. Limann, 30.02. J. H. Gladstone and W. Hibbert, unlike A. Heydweiller, found that the result depended on the concentration, and increased with concentration at first slowly and then rapidly. A. Hauke also observed that the result depended on the concentration. G. Limann discussed the relation between the index of refraction and the electrical conductivity of the soln. He also found for the **dispersion** at 18°, $(\mu_D - \mu_A)/C = 26.6$, and $(\mu_\beta - \mu_D)/C = 67.2$. A. Heydweiller also studied the optical dispersion of the soln. Observations on the optical properties of soln. in methyl alcohol were made by H. C. Jones and J. A. Anderson. Those of soln. in ethyl alcohol were examined by J. Malsch, J. M. Hiebendaal, E. Schaer, J. S. Anderson, J. H. Gladstone and W. Hibbert, F. G. Donnan and H. Bassett, G. Pellini and D. Meneghini, H. C. Jones and J. A. Anderson; of soln. in ether, by K. A. Hofmann and K. Ott, K. Ott, and W. J. Russell and W. J. Orsman; of soln. in acetone, by H. C. Jones and J. A. Anderson.

G. J. Elias observed that a half sat. soln. of ferric chloride exhibits no **magnetic birefringence**—*vide supra*, the hydrosol of ferric oxide. Like soln. of the other ferric salts, ferric chloride soln. show a negative **magnetic rotatory power**, and since water exerts a positive influence, the magnetic rotation of the plane of polarization of the soln. is only a little greater than the value for water. H. Becquerel observed the magnetic rotatory power, ω , referred to water unity, at 15° to 18° for soln. with less than 71 per cent. of FeCl_3 , and at a higher temp. for more conc. soln. in order to prevent the deposition of crystals :

FeCl_3	80	70.58	60.5	50 per cent.
ω	-23.11	-19.07	-15.584	-8.768
FeCl_3	33	16.5	8.25	2.06 per cent.
ω	-2.674	-0.116	+0.621	+0.936

The negative values increase at a faster rate than is proportional to the increase in the conc. of the soln., and the mol. magnetic rotation which with most substances is a constant, increases with increasing concentration; only in dil. soln. is the magnetic rotatory power constant. Observations were made by H. E. J. G. du Bois, G. Quincke, P. K. Pillai, E. Miescher, O. Schönrock, W. Stscheglaieff, and M. E. Verdet. C. E. Richards and R. W. Roberts gave, at 20° :

λ	6104	5780	5330	5105	4958
ω { 1.045 sp. gr.	0.0105	0.0117	0.0135	0.0145	0.0154
1.167 sp. gr.	-0.0009	-0.0019	-0.0050	-0.0099	—

The magnetic rotation changes from positive to negative with increasing concentration of the soln.; and with a soln. of sp. gr. 1.092, the rotatory dispersion curve changes markedly near 0.57μ —probably owing to a partial dehydration of the molecule of hydrated ferric chloride. The magnetic absorptions of ferric chloride and sulphate are the same.

L. R. Ingersoll studied **Kerr's effect**, and gave for **Verdet's constant**, in a magnetic field of 12,050 gauss, with soln. of 6.3 and 47.8 per cent. FeCl_3 , 0.061 and -0.0399 for $\lambda=8,000$; 0.0040 and -0.0215 for $\lambda=10,000$; and 0.0026 and -0.0110 for $\lambda=12,500$. The value of Verdet's constant was found by M. E. Verdet, and H. E. J. G. du Bois, to be unaffected by variations in the strength of the magnetic field up to 2400 gauss; and the latter was unable to confirm W. Stscheglaieff's observation that there is a considerable deviation with fields ranging from 9000 to 16,000 gauss. L. R. Ingersoll observed that Verdet's constant varies proportionally with the third power of the wave-length over the range $\lambda=7000$ to 13,500 Å. Observations on soln. in methyl alcohol were made by M. E. Verdet, G. Quincke, O. Schönrock, H. E. J. G. du Bois; in ether, by M. E. Verdet, and O. Schönrock. P. K. Pillai, and F. Allison and E. J. Murphy studied the magneto-optic properties of ferric chloride.

O. Stelling and F. Olsson studied the X-ray spectrum. A. E. Garrett found that ferric chloride at 355° emits in air **positive and negative ions**, which make the ambient air a conductor. O. W. Richardson suggested that the positive ions may be referred to the contamination of the chloride with potassium salts. The emission of positive ions by the salt was also discussed by O. Gossmann, H. Queren-gässer, G. C. Schmidt, and H. Geiger and K. Scheel, and the Becquerel effect, by J. Lifschitz and S. B. Hooghoudt. A. L. Hughes observed that ferric chloride exhibits a very feeble **photoelectric effect**, which, according to G. Dima, is smaller than is the case with ferrous chloride; and A. Pochettino, similarly with Hallwachs' effect. W. Zimmermann observed no perceptible photoelectric effect with aq. soln. of ferric chloride. M. Schneider discussed the photochemical reduction of ferric chloride. E. P. Perman showed that a little of the chloride is reduced by exposure to **canal rays** in air or in hydrogen; whilst K. Niederstadt found that **radium rays** are without action. For the decomposition in light, *vide infra*.

E. N. da C. Andrade found that a flame is coloured yellow by ferric chloride, and that the **flame spectrum** has bands in the red, green, and yellow. R. Zsigmondy showed that unlike soln. of ferrous chloride, the transparency of soln. of ferric chloride for **heat rays** is only a little smaller than is the case with water. J. S. Anderson observed that the mol. extinction coeff., k , of soln. of ferric chloride, containing C mols of FeCl_3 per litre, for ultra-red rays of wave-lengths, λ , are:

λ	7100	7880	8370	9000	9680	10,620	11,750 Å.
$k_{c=2.0}$	0.08	0.09	0.11	0.12	0.10	0.06	0.03
$k_{c=0.2}$	0.16	0.25	0.23	0.20	0.14	0.06	—

No change with ageing was observed. T. Dreisch observed a band with a maximum at 8300 Å. Not a tenth part of the energy is absorbed at the maximum that is absorbed in the maximum of the ferrous sulphate band. According to J. Königsberger and K. Küpferer, the **absorption spectrum** of the yellowish-red vapour of ferric chloride, at 250° , has a band in the blue and violet; and C. Sheard and C. S. Morris found a continuous band between 5900 Å. and 4800 Å. in the emission spectrum of ferric chloride. F. I. G. Rawlins and C. P. Snow found in the anhydrous crystals, an absorption band about 5000 Å., and one about 6200 Å. V. L. Bohnson and A. C. Robertson observed no bands in the absorption spectrum of aq. soln. of ferric chloride; H. C. Jones and J. A. Anderson said that the soln. are almost transparent for the whole of the visible spectrum; and B. E. Moore found that there is a sharp absorption band at the short-wave end with conc. soln., but with dil. soln. the edges of the band are not so clear. From the records of A. Byk and H. Jaffe, H. C. Jones and J. A. Anderson, S. M. Karim and R. Samuel, and G. P. Drossbach, it follows that the position of the absorption

band varies with the conc. of the soln. C. Lepière recommended a conc. soln. of chromic acid and ferric chloride to remove the orange rays. Observations on the absorption spectrum, and the mol. extinction coeff. were made by J. von Koczkas, G. Lemoine, T. Ewan, and R. A. Houstoun and C. Cochrane; V. L. Bohnson and A. C. Robertson's results are summarized in Fig. 559—*vide* the ferrates. J. S. Anderson gave for soln. with C mols of FeCl_3 per litre :

λ . . .	7170	6870	6530	5820	5290	4990	4340 A.
$k \begin{cases} C=2.0 \\ C=0.2 \end{cases}$. . .	0.08	0.09	0.11	0.17	0.9	5.7	—
	—	0.12	0.10	0.21	1.0	2.15	18.6

The effect of hydrolysis is shown by observations on freshly prepared soln., and on soln. aged 6 weeks, for $\lambda=5290$ A. :

C . . .	4	3	2	1.4	0.8	0.2	0.02
$k \begin{cases} \text{Fresh} \\ \text{Aged} \end{cases}$. . .	3.43	1.77	0.86	0.63	0.63	0.84	1.75
	2.37	1.26	0.63	0.51	0.52	0.81	0.75

G. Lemoine showed that Beer's rule applies approximately for conc. soln., but with decreasing concentration the rule fails. J. von Koczkas also noted the failure of Beer's law and of Lambert's law with soln. of ferric chloride owing to hydrolysis. B. E. Moore attributes the failure to the breaking down with dilution of strongly absorbent complexes into feebly absorbent ions. There are also disturbances due to the formation of intensely coloured, colloidal complexes by the hydrolysis of the aq. soln. Beer's rule also applies better for light of long wave-length than for light of short wave-length. The subject was also discussed by J. S. Anderson, U. Antony and G. Giglio, T. Ewan, H. C. Jones and J. A. Anderson, A. Müller, and S. U. Pickering. W. J. Russell and W. J. Orsman found that a soln. of ferric chloride sat. with hydrogen chloride has an absorption spectrum with bands extending to 7180, from 7000 to 6800, from 6620 to 6510, from 6310 to 6200, from 6030 to 5920, from 5500 to 5200, 5110 to 4970, and from about 4830 to about 4500. Excepting for the bands 6030 to 5920, and 5110 to 4970, the spectrum is similar to that observed with cobaltous chloride similarly treated. Similar remarks apply to ethereal soln. sat. with hydrogen chloride. H. C. Jones and J. A. Anderson observed that additions of calcium or aluminium chloride act somewhat similarly. Observations were also made by A. Byk and H. Jaffe, and G. Lemoine. O. Gossmann studied the emission of positive ions by heated ferric chloride; and A. Pochettino, the Hallwach's effect.

H. Querengässer measured the **electrical conductivity** of the vapour of ferric chloride—*vide supra*. According to W. Hampe, ferric chloride dissociates on heating to form some ferrous chloride, and it is therefore electrically conducting; but a soln. of dry ferric chloride in dry ether does not conduct. If a trace of moisture be present, the soln. is a conductor, and hydrogen is evolved at the negative pole, but no gas comes off from the positive pole; with more water, iron is deposited, but although hydrogen is evolved no ferrous chloride forms, as otherwise, owing to its insolubility in ether, it would be deposited on the negative pole, which is not the case. No chlorine is evolved, as it enters into secondary combination. Ferric chloride is therefore not an electrolyte, but when mixed with water it becomes one. This conversion is attributed to the formation of a compound, $\text{Fe}_2\text{Cl}_6\text{H}_6\text{O}_6\text{H}_6$, corresponding to the compound supposed to be formed with hydrochloric acid and water. Electrolysis would break it up into the groups 2Fe^{+++} and $6(\text{ClH.OH})$, which would fully explain the occurrence of many secondary reactions. Measurements of the electrical conductivity of aq. soln. were made by C. Cattaneo, and E. Wertyporoch and I. Kowalsky; and H. M. Goodwin gave for the eq. conductivity, λ of soln. with one eq. of ferric chloride in v litres of water, at 25° :

v . . .	9.90	19.80	39.6	79.2	158.4	316.8	633.6
λ . . .	81.5	96.7	113.0	130.3	148.3	166.3	181.8

R. Peters obtained analogous results. H. Mosler's values for the sp. conductivity

of soln. of ferric chloride are summarized in Fig. 578. The dotted line refers to the temp. coeff., α , of the conductivity. The conductivity increases to a maximum, with approximately $M\text{-FeCl}_3$, and it then decreases; the maximum is the more pronounced the higher is the temp. Observations were also recorded by H. C. Jones and co-workers, H. M. Goodwin and F. W. Grover, and A. Heydweiller. E. Moles and co-workers gave for the mol. conductivity, μ , mhos, of soln. with C mols of the salt in a litre. Similarly also for the temp. coeff., α , of the conductivity :

C		0.0507	0.2009	0.7379	1.4758	2.9515	3.9370
μ	0°	163	120.3	70.0	36.15	8.42	3.0
	18°	268.3	190.8	108.5	—	15.33	6.11
	25°	312.63	219.8	128.3	65.39	18.42	7.59
	35°	381.1	262.6	145.6	77.91	23.08	—
α	0° to 18°	2.71	2.52	2.40	2.42	3.23	3.70
	18° to 25°	2.18	2.02	1.83	1.79	2.61	3.08
	25° to 35°	1.98	1.81	1.62	1.75	2.19	—

The limiting value for the mol. conductivity of non-hydrolyzed ferric chloride at 25° for infinite dilution was found by N. Bjerrum to be $\mu_\infty=435$; and the limiting value for the eq. conductivity at 18° was found by A. Heydweiller, and G. Limann to be $\lambda_\infty=126.5$. E. Moles and co-workers showed that the temp. coeff. decreases with increasing concentration to a minimum, and then increases—*vide* Fig. 578—and the position of the minimum corresponds with the maximum in the conductivity curve. The effect of temp. on the conductivity was also measured by C. Cattaneo, H. C. Jones and co-workers, G. Malfitano and L. Michel, G. Malfitano, and H. Mosler. J. A. Fleming and J. Dewar observed that by cooling the soln. to -198° , it is almost completely non-conducting, for the resistance is 10,000 megohms at -198° , and nearly the same at -156° , and there is then an abrupt change, for it becomes 0.2 megohm at -115° . G. Berndt found that the effect of a magnetic field of 3000 gauss is less than 0.004 per cent. of the value of the conductivity.

H. C. Jones and C. M. Stine measured the effect of mixed soln. of aluminium and ferric chlorides. L. Kahlenberg and co-workers found the mol. conductivity, μ , of soln. of a mol of ferric chloride in v litres of solvent, at 25° , to be :

Methyl alcohol	v	3.20	12.81	51.24	204.96	819.83	1639.66
	μ	20.81	31.09	49.00	172.61	111.08	147.08

Observations with methyl alcohol were also made by H. C. Jones and C. F. Lindsay, and L. I. Shaw; on ethyl alcohol, by A. T. Lincoln, and C. Cattaneo; A. T. Lincoln found for allyl alcohol for $v=22.02$, 53.71 , and 115.6 at 25° , $\mu=17.42$, 23.03 , and 32.5 respectively; and for $v=20.02$ at 25° , 50° , 73° , and 80° , $\mu=17.42$, 34.62 , 43.63 , and 45.63 respectively; L. Kahlenberg and A. T. Lincoln, and A. T. Lincoln gave for soln. in benzyl alcohol for $v=88.06$ and 895.22 at 25° , $\mu=2.62$ and 6.31 respectively; and for $v=88.06$, at 25° , 54° , 85° , and 100° , $\mu=2.62$, 5.08 , 6.46 , and 7.19 respectively; L. Kahlenberg and A. T. Lincoln found soln. in glycol are good conductors; and for the sp. conductivity, κ mho, of soln. of C mol of FeCl_3 per litre, they gave for $C=0.000339$ at 0° , 2.8° , and 24.1° , $\kappa \times 10^9=0.0108$, 0.0115 , and 0.0708 respectively; for $C=0.00431$ at 0° , 10.8° , and 21.6° , $\kappa \times 10^9=0.132$, 0.339 , and 0.722 respectively; and for $C=0.0337$ at 0° , 13.0° , and 23.1° , $\kappa \times 10^9=0.512$, 1.44 , and 3.11 respectively. Observations on the conductivity of soln. in glycerol were also made by C. Cattaneo, and J. Timmermans. W. Hampe, and L. Kahlenberg and A. T. Lincoln said that a soln. of dry ferric chloride in dry ether is non-conducting, but C. Cattaneo found that the sp. conductivities of soln. of 0.0407 , 0.0079 , and 0.0042 mols FeCl_3 per litre are respectively 0.550 , 0.068 , and 0.0377 mho. The temp. coeff. is negative between 10° and 30° . J. Timmermans also studied the mol. conductivity; and H. E. Williams, the electrolysis of wet ethereal soln. L. Kahlenberg and A. T. Lincoln, L. Kahlenberg, and A. T. Lincoln found that soln. of a mol of ferric chloride in $v=4.37$, 21.32 , 81.88 , and 575.50 litres of paraldehyde at 25° has the respective mol. conductivities $\mu=9.81$, 16.91 , 19.16 , and 16.91 ; with soln. in salicylaldehyde, $v=20.39$, 81.38 , and 220.74 when $\mu=3.76$, 4.71 and 5.60 respectively; with furfural, $v=45.60$, 80.98 , and 149.21 when $\mu=20.78$, 22.20 , and 26.42 respectively; in the soln. in methylpropylketone, $v=13.64$, 100.71 , and 1074.27 when $\mu=28.25$, 42.75 , and 59.52 respectively; with soln. in acetophenone, when $v=23.46$, 65.77 , and 292.98 , then $\mu=10.28$, 11.59 , and 13.08 respectively; with soln. in amyl nitrite, when $v=21.34$, 69.46 , and 644.56 , $\mu=1.54$, 2.02 , and 3.73 respectively; with soln. in methyl thiocyanate, when $v=2.321$, 18.15 , and 24.68 , $\mu=27.20$, 39.63 , and 42.52 respectively; with soln. in ethyl thiocyanate, for $v=1.1146$, 8.865 , and 5.37 , $\mu=15.96$, 32.44 , and 42.43 respectively; with amyl thiocyanate, when $v=2.935$, 15.77 , and 193.5 , $\mu=8.32$, 13.06 , and 23.52 respectively; with ethyl isothiocyanate, when $v=3.039$, 6.793 , and 26.10 , $\mu=10.68$, 12.18 , and 11.59 respectively; with ethyl monochloroacetate, with $v=7.76$, 45.63 , and 152.55 , $\mu=12.45$, 14.78 , and 17.88 respectively; with ethyl cyanoacetate, with $v=15.30$, 44.64 , and 185.22 , $\mu=8.88$, 9.80 , and 11.57 respectively; with diethyl oxalate, when $v=13.15$, 42.29 , and 342.85 , $\mu=5.88$, 5.92 , and 7.70 respectively; with ethyl benzoate, when $v=20.54$, 174.28 , and 517.21 , $\mu=1.55$, 1.61 , and 1.91 respectively; with *m*-nitrotoluene, when $v=10.86$, 84.77 , and 814.8 , $\mu=6.86$, 12.55 , and 18.20 respectively; with *o*-nitrotoluene, when $v=10.94$, 74.28 , and 201.4 , $\mu=8.37$, 13.32 , and 15.24 respectively; with pyridine, when $v=6.06$, 24.56 , and 95.35 , $\mu=7.96$, 6.85 , and 6.41 respectively; and L. Kahlenberg and O. E. Ruhoff found that with amylamine, when $v=5.021$, 18.34 , and 27.05 , $\mu=0.217$, 0.138 , and 0.086 respectively. A. P. Julien measured the conductivity of soln. in selenium oxychloride; and E. Wertyporoch and I. Kowalsky, in various non-aqueous solvents.

When an aq. soln. of ferric chloride is evaporated, hydrochloric acid is evolved, and hydrated ferric oxide or oxychloride is deposited; H. W. B. Roozeboom observed that when the aq. soln. is evaporated on a water-bath, it cannot be

concentrated much farther than $\text{FeCl}_3 \cdot 2.5\text{H}_2\text{O}$. The **hydrolysis** is represented by the equation: $\text{FeCl}_3 + 3\text{H}_2\text{O} \rightleftharpoons \text{Fe}(\text{OH})_3 + 3\text{HCl}$; and, according to E. Stirnemann, this reaction occurs at temp. below 200° , or at the most 350° , but at higher temp. reactions represented by $\text{FeCl}_3 + \text{H}_2\text{O} = \text{FeOCl} + 2\text{HCl}$, and $2\text{FeCl}_3 + 3\text{H}_2\text{O} = \text{Fe}_2\text{O}_3 + 6\text{HCl}$ may occur. According to F. W. C. Krecke, all aq. soln. of ferric chloride are hydrolyzed when heated, and this the more the higher the temp. Soln. with over 4 per cent. of ferric chloride can be heated to 100° without decomposition, but in a sealed vessel, at a higher temp., more or less complete hydrolysis occurs. As the soln. becomes darker in colour, T. Graham's soluble hydrated ferric oxide is formed, and it is precipitated by alkali salts; and if the soln. with 4 to 32 per cent. of ferric chloride is not heated above 100° , the hydrolysis which occurs is reversed as the soln. cools, and with soln. having 1 to 4 per cent. ferric chloride, the re-combination of the products proceeds slowly as the soln. is cooled, but if the soln. has less than 1 per cent. of ferric chloride, re-combination of the products of hydrolysis does not occur as the soln. cools. If the soln. with over 1 per cent. of ferric chloride be heated for a long time, or heated to a higher temp., an insoluble oxychloride is precipitated, and this goes into compact, black, anhydrous, ferric oxide. If the soln. with less than 1 per cent. of ferric chloride be heated for a long time, L. P. de St. Gilles' sparingly soluble hydrated oxide is formed, and this makes the soln. turbid. These results are summarized in Table XCI.

TABLE XCI.—THE ACTION OF HEAT ON AQUEOUS SOLUTIONS OF FERRIC CHLORIDE.

Observations on the hydrolysis and ageing of ferric chloride in aq. soln. were made by R. Phillips, H. de Sénarmont, J. M. Ordway, N. N. Petin and co-workers, L. Liechti and W. Suida, Z. H. Skraup and co-workers, R. Haller, E. Lesche, N. Sahlbom, G. Jander and W. Scheele, E. Erlenmeyer, M. Gieseler, M. Goble, B. Sandrock, A. Tian, K. Schuwirth, J. Attfield, B. de Buisson, G. C. Wittstein, C. R. Fresenius, H. Ditz, H. M. Vernon, C. R. C. Tichborne, A. Vogel, W. Bachmann, F. W. C. Krecke, and D. Tommasi.

W. Spring noted that **Tyndall's optical test**—1. 13, 7—shows that dil. aq. soln. are not optically empty, even though in diffuse daylight they seem quite clear. The Tyndall effect is lessened by the addition of dil. hydrochloric acid, and it disappears if conc. hydrochloric acid be added. D. Vorländer, and W. Bachmann found with the ultramicroscope that the soln. are almost free from colloidal particles, but with a dilution of $0.0005N\text{-FeCl}_3$, and using polarized light, a discontinuity can be detected. This is due to the presence of colloidal ferric hydroxide. These particles appear larger if sodium chloride be added, and disappear if hydrochloric acid is added. E. Lesche observed that during the ageing of the soln. the particles dehydrate and become increasingly lyophobic—the change is irreversible.

The change which occurs in the electrical conductivity of dil. aq. soln. of ferric chloride by ageing was attributed by G. Vicentini to hydrolysis, and this was confirmed by G. Foussereau, E. Puxeddu, etc. U. Antony and G. Giglio observed

that whilst a freshly-prepared soln. with less than 1.1 per cent. of ferric chloride, is colourless when viewed in a 40-cm. tube, it acquires a yellow colour on standing for some hours, and the colour becomes deeper 48 hrs. after the soln. has been prepared. Soln. with less than 0.00083 per cent. of FeCl_3 show no coloration with potassium ferrocyanide. The facts are here explained by assuming that in aq. soln., ferric chloride is hydrolyzed: $\text{FeCl}_3 + 3\text{H}_2\text{O} = 3\text{HCl} + \text{Fe}(\text{OH})_3$. L. Vanzetti illustrated the hydrolysis by filling a tube about three-quarters of its length with a hot, 5 to 10 per cent. soln. of gelatin rendered faintly pink by a trace of alkali and phenolphthalein. When the gelatin has "set," a 10 per cent. soln. of ferric chloride is added. As diffusion proceeds, two layers appear: (i) The lower colourless layer is due to the more rapid diffusion of the hydrochloric acid produced by the hydrolysis, and (ii) an upper, more or less opaque layer of brown hydrated ferric oxide. E. Moles and co-workers found that the conductivity of 0.1M- FeCl_3 remained constant for about a month, but A. Quartaroli observed that a 0.07M-soln., at 25°, increased about 3.5 per cent. during 1 month, and 3.9 per cent. during 3 months. H. M. Goodwin found that when a neutral soln. of ferric chloride

FIG. 579.—The Effect of Time on the Electrical Conductivity of Solutions of Ferric Chloride.

is progressively diluted, the soln., colourless at first, soon becomes yellow, and the mol. conductivity increases at the same time. The mol. conductivity at first assumes a constant value—*quiescent period*—for dilutions ranging up to 0.001M- FeCl_3 , but with greater dilutions, the conductivity changes with time as illustrated in Fig. 579. The curves in this diagram show that (i) the mol. conductivity of dil. soln. increases with time; (ii) the rate of increase rapidly increases with dilution; (iii) the increase in the conductivity does not begin at once, but only after the lapse of a definite interval of time; (iv) the initial lag, or the quiescent period, increases as the conc. of the soln. increases; (v) the time required for equilibrium increases enormously with increasing concentrations; and (vi) the reaction goes slowly at first—*primary hydrolysis*—then proceeds with increasing rapidity—*secondary hydrolysis*—and afterwards slowly until equilibrium is attained. Analogous results were obtained by G. Bongiovanni, C. Cattaneo, A. Dumansky, T. C. Fitzpatrick, G. Foussereau, A. Lottermoser and E. Lesche, E. Heymann, H. C. Jones and co-workers, W. Jufereff, G. Malfitano, G. Malfitano and L. Michel, R. Peters, E. Puxeddu, A. Tian, G. Vicentini, and C. L. Wagner. The results of H. M. Goodwin and F. W. Grover are plotted in Fig. 579. When the temp. is raised the quiescent period is shortened, the period of acceleration is hastened, and the time required for equilibrium is shortened. A fall of temp. from 25° to 10° has nearly the same effect in retarding the reaction as increasing the concentration about three times; lowering the temp. to 0°, retards the reaction as much as increasing the concentration 15 to 20 times. As emphasized by G. Malfitano, and G. Malfitano and L. Michel, L. Michel, E. Heymann, B. E. Moore, etc., after the quiescent period during which no hydrolysis occurs, the hydrolysis may be assumed to occur in two stages. The first stage of the hydrolysis—or *primary hydrolysis*—is attended by a change in the properties of the soln.; for instance, the electrical conductivity increases far more than corresponds with the ionization of the ferric chloride. According to E. Heymann, the ferric ions begin to disappear, and more mobile hydrogen ions take their place. H. M. Goodwin observed that, according to the degree of dilution, the soln. are at first more or less colourless, and the colour does not change so long as the conductivity is constant. U. Antony

and G. Giglio found that a freshly-prepared 0.02 to 0.00004 *M*-soln. does not redden litmus, showing that hydrolysis, recognizable by this test, has taken place; it is not rendered turbid by coagulative influence of sodium chloride; it reacts with hydrogen sulphide; and it gives a blue precipitate with potassium ferrocyanide. W. Spring found that when a current of air is passed through a soln. of greater concentration than *M*-FeCl₃, some hydrogen chloride passes off, indicating that even with these soln. some hydrolysis has occurred. G. Malfitano and L. Michel showed that with very dil. soln. the increase in the primary hydrolysis produced by dilution, or by a rise of temp. can be reversed by gentle evaporation or cooling.

In the second stage of the hydrolysis—or *secondary hydrolysis*—there is a gradual change in the properties of the soln. until a state of equilibrium is attained. The rate at which the state of equilibrium is inaugurated is determined by the temp. and concentration of the soln., as well as by the presence of certain foreign substances. The duration, *t*, of the period of secondary hydrolysis was found by H. M. Goodwin, H. M. Goodwin and F. W. Grover, G. Malfitano, C. L. Wagner, and G. Fousseureau to be dependent on the concentration of the soln.; expressing the concentration, *C*, in mols of FeCl₃ per litre, H. M. Goodwin found that:

<i>C</i>	.	.	.	0.0006	0.0012	0.0024	0.01515
<i>t</i>	.	.	.	1 min.	15 min.	25 min.	3 days

With the most conc. soln., the time occupied by the second stage of the hydrolysis is inordinately long. According to G. Malfitano, G. Fousseureau, and E. Puxeddu, the time is also abbreviated by raising the temp. Thus, H. M. Goodwin and F. W. Grover found that with 0.00044 *M*-FeCl₃, the change was very rapid at 25°; it occupied 5 mins. at 15.5°; and a day at 0°; whilst with a 0.00088 *M*-soln., no perceptible change was observed during 4 days at 0°. The time, *t*, required for the soln. to attain a state of equilibrium was found by H. M. Goodwin to be 3 hrs. at 25° for a 0.00010 *M*-soln., and about a week for a 0.00061 *M*-soln.; by H. M. Goodwin and F. W. Grover, between 8 and 24 hrs. for a 0.00005 *M*-soln. at 0°, and 1.5 hrs. at 24.92°; 2 hrs. for a 0.00015 *M*-soln. at 25.12°, and a day for a 0.00030 *M*-soln. at 15.7°; by A. Quartaroli, 3 hrs. at 25° for a 0.00011 *M*-soln.; by C. L. Wagner, between 1 and 3 days for a 0.00042 *M*-soln. at 25°; by E. Heymann, many months for a 0.005 soln. at 20°, and 1 to 2 months at 37°; and by G. Fousseureau, for a 0.01 *M*-soln., 30 mins. at 100°, 80 mins. at 84°, and above 74 days at ordinary temp. G. Fousseureau, E. Heymann, G. Malfitano, and G. Malfitano and L. Michel found that the process of hydrolysis is reversible when it has been slowly attained. The same final state can be obtained by starting from either end of the system. The hydrolysis $\text{FeCl}_3 + 3\text{H}_2\text{O} \rightleftharpoons 3\text{HCl} + \text{Fe}(\text{OH})_3$ is displaced from left to right by raising the temp. or diluting the soln.; and when the state of equilibrium has been displaced from left to right by raising the temp., the original state is restored when kept at ordinary temp. G. Fousseureau observed that the state of equilibrium is reversibly displaced in favour of increasing hydrolysis by raising the pressure; and A. Dumansky found that centrifuging the soln. in equilibrium, results in extending the hydrolysis. B. E. Moore observed that light had no effect on the hydrolysis, but G. Fousseureau said that some of the hydrosol of ferric hydroxide may be coagulated, and H. Schild, and P. Roesser added that the coagulation occurs only when some ferrous chloride is present. S. S. Bhatnagar and co-workers found that exposure to X-rays favours the hydrolysis. H. M. Goodwin and F. W. Grover observed that a magnetic field of 1850 gauss had no perceptible influence on the hydrolysis.

The presence of hydrochloric acid hinders the hydrolysis, and, as shown by A. Byk and H. Jaffe, if a soln. of ferric chloride be diluted until it is colourless, and conc. hydrochloric acid be added, the soln. assumes the brown colour characteristic of molecular ferric chloride. G. Malfitano and L. Michel showed that the initial quiescent period of constant conductivity increases with the proportion of added hydrochloric acid, and, other things being equal, the proportion of acid required

to render the soln. stable increases considerably with the temp. and varies slightly with the conc. of the ferric chloride. During the hydrolysis of a ferric chloride soln., a considerably larger quantity of hydrochloric acid can be formed than would have rendered the soln. stable if added at first, the conductivity of hydrolyzed soln. rising to values greater than those of soln. initially treated with acid. Moreover, small additions of acid only retard hydrolysis at the beginning, they afterwards accelerate it. The increase in conductivity on heating, and its decrease subsequently, diminish as the quantity of acid added increases. The conclusion is drawn that the products of hydrolysis are not constant in composition, only those first formed being easily reconverted into FeCl_3 by the hydrochloric acid present, the action of the acid becoming more and more difficult as the hydrolysis progresses, and, further, that the products of hydrolysis are rendered more resistant by the presence of hydrogen chloride. The amount of hydrochloric acid which, added at the beginning, renders the soln. stable, when added during hydrolysis, not only does not restore the soln. to its original condition, but does not stop the hydrolysis. These phenomena are best explained by the hypothesis that the colloid formed from the products of hydrolysis is composed of complex ions. The precipitation of ferric colloids by anions diminishes as the valency of the latter increases, and it is inferred that the anions act similarly in preventing the formation of the colloid. The activity of nitric, oxalic, hydrochloric, sulphuric, arsenic, or phosphoric acid at conc. $0.001N$ -, $0.004N$ -, and $0.01N$ -, on $\frac{1}{150}N$ - FeCl_3 , in increasing the conductivity is a function of the time; and their activity in retarding the progress of irreversible hydrolysis, is partly dependent on their degree of ionization, but the influence of the anion is shown by differences in the activity between equally ionized acids, such as hydrochloric and nitric acids, and particularly by the activity of oxalic acid which is much greater than would be anticipated from its ionization coeff. As the concentration of the acid diminishes, the influence of the H^+ -ions becomes negligible, and that of the polyvalent anions preponderant—probably through the replacement of chlorine in ferric chloride, and the formation of molecules with a smaller tendency to dissociate. The increase with time of the conductivity of the $\frac{1}{150}N$ - FeCl_3 , containing variable proportions of phosphoric acid is least when the conc. of the acid is $0.004N$ - H_3PO_4 ; at lower conc., the hydrolysis and formation of colloid are only slackened, and at higher conc., the formation of colloid is definitely prevented, the conductivity meanwhile increasing with time. This can be explained only by the quantity of free hydrochloric acid displaced by the phosphoric acid. The phenomenon becomes more evident at 100° ; soln. of ferric chloride containing an eq. of phosphoric acid, when heated at this temp., give a white positive colloid containing iron and phosphoric acid, which tends to disappear on cooling the more easily the greater is the conc. of the ferric chloride. The formation of the hydroxide colloid is prevented when the ratio $\text{Fe} : \text{PO}_4$ is $1 : 6000$ at 18° ; $1 : 200$ at 50° ; and $1 : 16$ at 100° . An increase in the temp. and dilution affects only the irreversible, not the reversible, hydrolysis. It is concluded that the ferric ions become less apt to form complex ions, $(\text{Fe}[\text{Fe}(\text{OH})_3]_n)$, as the valency of the accompanying anions increases, and the micro-cells, conceived as complex ions of large dimensions (n being very great), protect the mols of the hydroxide from the hydrochloric acid. Consequently, if these complex ions cannot be formed, the irreversible hydrolysis is impeded. G. Malfitano and L. Michel conclude that the phenomena of the colloidal state are more pronounced and appear more rapidly in soln. of ferric chloride to which potassium chloride has been added than in soln. of ferric chloride alone. The rate of hydrolysis of the ferric chloride depends on the proportion of potassium chloride present. The size of the micro-cells of ferric hydroxide is increased by the addition of this salt. The number of ferric ions being diminished, there are fewer centres of attraction for the ferric hydroxide molecules, and consequently the individual cells are more voluminous. The chlorides of sodium, ammonium, barium, and magnesium, and also potassium nitrate, behave in a similar manner. Mercuric chloride, on the other hand, being a

non-electrolyte, has no appreciable influence on the course of the hydrolysis. Salts containing polyvalent negative ions, such as potassium sulphate, behave like the polyvalent acids previously studied in hindering hydrolysis. The influence of potassium sulphate on the hydrolysis was examined by G. Malfitano and L. Michel, A. Quartaroli, and C. L. Wagner; of sodium, barium, and aluminium chlorides, by T. Katsurai; and the action of neutral salts, by G. Malfitano, and G. Malfitano and L. Michel. C. L. Wagner, A. Tian, and N. R. Dhar and D. N. Chakravarti found that gelatine retards the hydrolysis; so does glycerol; and, according to R. Phillips, sugar. The action of silica-gel was studied by A. Tian, and N. R. Dhar and D. N. Chakravarti.

When the dil. aq. soln. of ferric chloride is aged, or heated, a hydrogel of ferric hydroxide (*q.v.*) is formed. H. M. Goodwin and F. W. Grover found that the effect of lowering the temp. is to diminish the rate of formation of the colloidal hydrated ferric oxide, and of the separation of the hydrogel. Soln. of 0.02*N*-, and 0.002*N*-FeCl₃ remained quite clear when kept on ice for 2 weeks; but a 0.0075*N*-soln. became very turbid in less than 4 days at 25°, slightly turbid in the same time at 15°; and it remained clear at 0°. The subject was investigated by A. Béchamp, H. Debray, H. W. Fischer, H. M. Goodwin and co-workers, F. W. C. Krecke, G. Malfitano, T. Katsurai, P. Nicolardot, S. U. Pickering, C. R. C. Tichborne, H. B. Weiser, etc. It was formerly thought that the formation of the precipitate was a measure of the progress of the hydrolysis; but E. Heymann and others have emphasized the fact that the coagulation of the hydrosol is not related with the hydrolysis in any simple manner. The conditions necessary to ensure the reproduction of phenomena have not yet been all recognized.

According to H. M. Goodwin, the phenomena which attend the primary hydrolysis of the soln. of ferric chloride can be explained by assuming that a reaction symbolized: $\text{FeCl}_3 + \text{H}_2\text{O} = \text{Fe}(\text{OH})^{++} + \text{H} + 3\text{Cl}^-$, or $\text{Fe}^{+++} + \text{H}_2\text{O} = \text{Fe}(\text{OH})^{++} + \text{H}^+$, occurs. The base $\text{Fe}(\text{OH})^{++}$ may be formed in soln. in accord with $\text{Fe}(\text{OH})_3 \rightleftharpoons \text{Fe}(\text{OH})^{++} + 2\text{OH}^-$, and the supposed step-by-step ionization of polybasic acids. The first result of diluting a soln. of ferric chloride, as shown by conductivity measurements, is to inaugurate the reaction: $\text{FeCl}_3 + \text{H}_2\text{O} \rightleftharpoons \text{Fe}(\text{OH})\text{Cl}_2 + \text{HCl}$. B. E. Moore considered that optical observations supported H. M. Goodwin's views of the formation of $\text{Fe}(\text{OH})\text{Cl}_2$, as an intermediate product of the hydrolysis; but C. L. Wagner doubted the hypothesis. W. C. Bray and A. V. Hershey studied the system: $\text{Fe}^{+++} + \text{Cl}^- = \text{FeCl}^{++}$. According to H. M. Goodwin, assuming that the $\text{Fe}(\text{OH})^{++}$ -ions are colourless, the hypothesis is in agreement with the fact that the first effect of the dilution is to reduce the coloration of the soln. The increase of the conductivity is attended by a deepening of the colour of the soln. until the colour is the same as that of the colloidal hydroxide obtained by T. Graham, $n\text{Fe}(\text{OH})^{++} + 2n\text{H}_2\text{O} = \{\text{Fe}(\text{OH})_3\}_n + 2n\text{H}^+$. It is here assumed that the colloidal hydroxide is a polymeric form of the normal hydroxide. A. P. Sabanéeff favours the assumption that the colloid has the formula $\text{FeCl}_3 \cdot n\text{Fe}(\text{OH})_3$, where *n* is very great. The reaction at this stage is almost irreversible.

According to C. L. Wagner, the hydrolysis is very rapid, and the hydrated oxide is liberated as a highly dispersed phase, and the liberating acid is completely adsorbed on the enormous surface of this dispersed phase. As the particles increase in size in the process of time, the surface of the dispersed phase rapidly diminishes, and the adsorbed acid enters the soln., and this is taken to explain the increase in conductivity which occurs when the requisite dilution is reached. The hypothesis is supported by an ultra-microscopic examination of dil. soln. of ferric chloride. According to E. Heymann, when a freshly prepared soln. of ferric chloride is allowed to stand, the whole of the products of hydrolysis pass through an ultra-filter, but the degree of dispersion decreases with increasing age, and the proportion of the iron finally in the colloidal state increases with a rise in temp. and with a decrease in the conc. of the salt. This quantity may correspond

with an actual equilibrium because if a ferric chloride soln. be heated at 80° for 45 mins., whereby the hydrolysis is almost completed, and then aged at 20° or 37° , the amount of colloid ultimately approximates to that corresponding with the final temp. On the other hand, there is less chlorine in the colloid produced at 80° than in those produced at lower temp., and the amount does not change on cooling. The increase in the conductivity of the chloride soln. with age runs parallel with the colloid content except immediately after the soln. has been prepared, when the conductivity increases the more rapidly, as would be expected in view of the initial high degree of dispersion of the products of hydrolysis. The micelles themselves possess a measurable conductivity, but although with increasing age of the soln. they increase in quantity, their relative contribution to the conductivity of the system diminishes. This may be due in part to changes in dispersion, yet chemical changes are also involved, since the amount of chlorine falls at the same time, the composition of the final products of slow hydrolysis corresponding, not with a hydroxide, but with an oxychloride. As suggested by P. Nicolardot, it appears likely that the first product of hydrolysis is an oxychloride of the type $\text{FeCl}_n\text{Fe}(\text{OH})_3$, where n is probably less than 9. The mols. of this compound tend to associate, *i.e.* coagulate, and react with water with the elimination of hydrogen chloride and the formation of secondary oxychlorides which increase in complexity until their mols. attain colloidal dimensions. The original state of equilibrium is consequently disturbed, and more and more ferric chloride is hydrolysed—*vide supra*, the hydrated oxide.

E. Heymann observed that the relation: $[\text{HCl}]^3 = K[\text{FeCl}_3]$ is only approximate in the case of colloidal ferric hydroxide, and hydrochloric acid, because, for a given concentration, the amount of ferric chloride formed increases with the concentration of the ferric hydroxide. The active mass of the colloidal product of the hydrolysis of ferric chloride is not constant, but increases with the concentration of the colloid. The reaction between colloidal ferric hydroxide and hydrochloric acid takes place, not only on the surface of the particles, but also within the surface. The equilibrium is also influenced by the degree of dispersion of the ferric hydroxide: thus, coarsely dispersed ferric hydroxide is in equilibrium with a smaller concentration of ferric chloride than the highly dispersed colloid. The dispersity varies with age, and by altering this condition micelles of different chemical composition can be produced. The micelles richest in chlorine are obtained by the ageing of ferric chloride solutions and those poorest in chlorine by mixing ferric hydroxide sol with hydrochloric acid.

The hypothesis of C. L. Wagner on the period of acceleration in the conductivity of the soln. was discussed by A. Quartaroli, A. Tian, E. I. Spitalsky and co-workers, and U. Antony and G. Giglio. The hypothesis of H. M. Goodwin, that during the primary hydrolysis $\text{Fe}(\text{OH})^{++}$ -ions accumulate in the system, involves the further assumption that as the hydrolysis proceeds, the reaction: $\text{Fe}(\text{OH})^{++} + 2\text{H}_2\text{O} = \text{Fe}(\text{OH})_3 + 2\text{H}^+$ is inaugurated. The initial lag, and the acceleration in the rate of the reaction are attributed to the rate of formation of the colloidal hydroxide being dependent on the presence of a certain amount of the colloid itself, which acts as in the analogous case when the rate of crystallization is a function of the number of nuclei about which crystals can form. This hypothesis is supported by the observation that an addition of less than 2 eq. per cent. of the colloidal hydroxide to 0.0075N- FeCl_3 at 25° accelerates the reaction to a marked degree. The observed initial lag of 20 mins'. duration is almost entirely eliminated. The increase in the initial rate of the reaction is approximately proportional to the conc. of the added colloid. B. E. Moore found that the hydrated oxide prepared by dialysis is less active than that prepared by the hydrolysis of ferric chloride. The greater speed of the reaction in dil. soln. is attributed to the presence of a larger proportion of $\text{Fe}(\text{OH})^{++}$ -ions, and of colloidal ferric oxide. The hypothesis that the secondary period is due to the passage of Fe^{+++} -ions, to non-ionized, colloidal hydroxide was discussed by U. Antony and G. Giglio, N. R. Dhar and

D. N. Chakravarti, H. M. Goodwin, J. Traube and W. von Behren, E. Heymann, G. Malfitano, G. Malfitano and M. Sigaud, M. Neidle, and A. Tian.

Other interpretations of the mechanism of the hydrolysis have been given. W. Spring, and W. Jufereff favoured the assumption that the ferric chloride dissociates in soln. the same as it does in the gaseous state, to form ferrous chloride and chlorine, $\text{Fe}_2\text{Cl}_6 \rightleftharpoons \text{Fe}_2\text{Cl}_4 + \text{Cl}_2$, or $\text{Fe}_2\text{Cl}_4 \cdot \text{Cl}_2$, and that the chlorine then reacts with water to form hydrogen chloride and oxygen; and that the latter combines with ferrous chloride to form the oxychloride, Fe_2OCl_4 , until the equilibrium $2\text{FeCl}_2 + \text{H}_2\text{O} + \text{Cl}_2 \rightleftharpoons \text{Fe}_2\text{OCl}_4 + 2\text{HCl}$, is attained. This is supposed to explain the augmented conductivity of soln. of concentration greater than 3.6 litres per mol. H. Querengässer measured the electrical conductivity of the vapour of ferric chloride. A. Dumansky and T. A. Granskaya measured the difference of potential established when electrodes of unequal surface are set up in a cell with ferric ions to which aq. ammonia is progressively added.

The **degree of hydrolysis** of aq. soln. of ferric chloride has been measured, but the soln. in all cases have probably not been in a state of equilibrium. F. W. C. Krecke studied the process of hydrolysis by measuring the sp. gr. of the soln.; F. L. Browne and J. H. Mathews, and G. Lemoine, the heat of dilution; and H. M. Goodwin, the lowering of the f.p. of the soln. U. Antony and G. Giglio made colorimetric observations on the percentage degree of hydrolysis, β , with soln. containing C mols per litre, and found, at 12° after 48 hrs.:

C	.	.	0.020466	0.006822	0.002047	0.001023	0.000512	0.000256
β	.	.	0.6	23.55	45.25	56.12	65.74	79.03

B. E. Moore studied the process by measuring the absorption spectrum, and T. Ewan, the extinction coeff. In the latter case, with soln. aged for many weeks at 15° to 16° :

C	.	.	0.005050	0.002525	0.001263	0.000505	0.000101	0.00002525
β	.	.	36.83	50.10	64.77	82.7	86	100

H. M. Goodwin calculated from the electrical conductivity at 25° the value β , on the assumption that the reaction is $\text{FeCl}_3 + \text{H}_2\text{O} = \text{Fe}(\text{OH})^{++} + 3\text{Cl}' + \text{H}'$; and the value β_2 on the assumption that the reaction is $\text{FeCl}_3 + 3\text{H}_2\text{O} = \text{Fe}(\text{OH})_3 + 3\text{HCl}$ —*vide infra*. The results were also re-calculated by N. Bjerrum. G. Wiedemann based his calculations on his measurements of the molecular magnetism of the soln. Calculations based on measurements of the action of the soln. on iodides were made by N. Sasaki; on the activity of chlorides, by F. L. Browne; on the decomposition of diazoacetic ether, by A. Quartaroli; on the hydrolysis of methyl acetate, by G. Carrara and G. B. Vespignani; on the inversion of cane-sugar, by A. Fodor and A. Rosenberg, and L. Bruner; and on the products of ultra-filtration, by E. Heymann. J. N. Brönsted and K. Volqvartz studied the acid hydrolysis of the salt.

Attempts have been made by F. L. Browne, N. R. Dhar and G. Urbain, H. M. Goodwin, H. C. Jones and co-workers, R. Lorenz, R. Peters, and N. Sasaki to calculate the **degree of ionization**, α , of the salt in soln. The results are complicated by the ionization of the products of the hydrolysis. On the assumption that the ionization and hydrolysis proceed in accord with the reactions (i) $\text{FeCl}_3 \rightleftharpoons \text{Fe}^{+++} + 3\text{Cl}'$; and (ii) $\text{FeCl}_3 + \text{H}_2\text{O} \rightleftharpoons \text{Fe}(\text{OH})^{++} + \text{H}' + 3\text{Cl}'$, H. M. Goodwin showed that for equilibrium, the soln. contains $1-\alpha-\beta$ mol of FeCl_3 ; α mol of Fe^{+++} ; 3α mols of Cl' ; β mol of $\text{Fe}(\text{OH})^{++}$; β mol of H' ; and 3β mol of Cl' . Measurements of the electrical conductivity on the f.p. of the soln. show that with soln. of eq. concentration C :

C	.	.	0.30	0.15	0.075	0.030	0.015	0.0075	0.0030	0.0015
α	.	.	73	77	74	50	35	24	10	5
β	.	.	—3	2	11	37	53	67	84	91
β'	.	.	—1	1	4	12	18	22	28	31

where β' denotes the percentage degree of hydrolysis on the assumption that the reaction is $\text{FeCl}_3 + 3\text{H}_2\text{O} = \text{Fe}(\text{OH})_3 + 3\text{H}^+ + 3\text{Cl}^-$. The values of β' are taken to show that the assumed reaction is absurd since the hydrolysis would remain nearly constant with increasing dilution. The values of β are taken to be in agreement with the assumption that the hydrolysis proceeds in accord with equations (i) and (ii). W. Hittorf gave 0.254 for the **transport number** of the Fe^{+++} -ion in 6.02*N*- FeCl_3 , and 0.400 in 0.705*N*- FeCl_3 ; whilst K. Hopfgartner gave 0.384 for 0.137*N*- FeCl_3 , and 0.359 for 0.444*N*- FeCl_3 , and calculated for infinite dilution 0.396. The acidity of the soln. had no perceptible influence on the results.

H. C. Jones and co-workers calculated the **degree of hydration**, that is, the **solvation**, of the salt in aq. soln., and found that if n denotes the number of mols of H_2O taken up by a mol of FeCl_3 , in soln. with C mols of FeCl_3 per litre, at 0° :

C	0.2	0.4	0.6	0.8	1.0	1.2	1.3617
n	61.0	50.7	44.8	39.6	35.4	32.1	29.5

From his observations on the transport numbers, K. Hopfgartner calculated that in a feebly acidified soln. of 0.137*N*- FeCl_3 , the Cl^- -ions are each loaded with 6 mols. of H_2O , and each Fe^{+++} -ion with 64 mols.; the observations of W. Manchot and co-workers on the solubility of acetylene, indicate that each molecule of FeCl_3 in soln., with 1.3433 to 2.1558 grms. FeCl_3 per litre, is loaded with 20.2 to 16.8 mols. of H_2O . A. E. Oxley's, and A. Smits and co-workers' observations on the viscosity; P. P. von Weimarn's observations on the cooling of the soln. to liquid air temp.; A. Brann's, and J. H. Walton and A. Brann's observations on the velocity of freezing; and H. G. Byers and C. H. Walter's, on electro-endosmosis, all agree that the salt is hydrated in aq. soln. L. W. Elder studied the electro-metric titration of soln. of ferric chloride by soln. of sodium hydroxide.

The **electrolysis** of soln. of ferric or ferrous chloride has been discussed in connection with the preparation of iron. Observations were made by H. Buff, A. Geuther, W. Hampe, W. Hittorf, S. I. Levy and G. W. Gray, T. P. McCutcheon and E. F. Smith, J. H. Paterson, etc. F. G. Donnan and H. Bassett found that with soln. of ferric chloride in conc. hydrochloric acid, a brownish-yellow liquid accumulated about the anode indicating the existence of complex iron anions. Z. Karaoglanoff studied the influence of diffusion currents on the electrolytic reduction; H. G. Byers and C. H. Walter, the electro-endosmose, that is, the motion of the electrolyte apart from the movements of the ions; A. Schukareff, the magnetic effect which occurs when the electrolysis occurs in a magnetic field of 2000 to 7000 gauss; M. le Blanc, the polarization; C. Baillod, the depolarizing action of ferric chloride in the cell $\text{Al}_{\text{amalgam}} | \text{N-H}_2\text{SO}_4, \text{NaCl}_{\text{sat. soln.}} | \text{C}$; L. Riéty, the potential difference between a soln. in a capillary at 25 atm. press., and the emerging soln.; and A. Finkelstein, the **decomposition voltage**, where with 0.1*N*-, 0.01*N*-, and 0.001*N*- FeCl_3 , the voltages were respectively -0.82, -0.97, and -0.75. E. Baur observed that the difference in the potential of a soln. against platinum when illuminated and when in darkness is really the result of a small temp. effect. N. Kameyama and K. Takahashi studied the electro-reduction of the salt.

The **electromotive force**, etc., of various cells with an electrolyte containing ferric chloride have been described. Thus, W. E. Case studied the cell $\text{C} | \text{FeCl}_3 | \text{Pt}$; H. Buff, the cells $\text{Zn} | \text{H}_2\text{SO}_4 | \text{FeCl}_3 | \text{C}$, and $\text{Zn} | \text{NaCl} | \text{FeCl}_3, \text{HCl} | \text{C}$; A. von Eccher, $\text{Zn} | \text{H}_2\text{SO}_4 | \text{FeCl}_3 | \text{C}$, and $\text{Zn} | \text{H}_2\text{SO}_4 | \text{FeCl}_3 | \text{Pt}$; T. Moore, $\text{Zn} | \text{H}_2\text{SO}_4 | \text{FeCl}_3 | \text{Pt}$ or C ; E. Duchemin, $\text{Zn} | \text{FeCl}_3(\text{Br}) | \text{H}_2\text{SO}_4 | \text{C}$; E. Petersen, $\text{Zn} | \text{NaCl} | \text{FeCl}_3 | \text{Cl}$; H. N. Warren, $\text{Zn} | \text{FeCl}_3, \text{Br} | \text{C}$; L. Kahlenberg, $\text{Pt} | 0.3\text{N-FeCl}_3 | \text{N-KCl}, \text{Hg}_2\text{Cl}_2 | \text{Hg}$, and $\text{Pt} | 0.3\text{N-FeCl}_3 | 0.375\text{N-FeCl}_3$ in amyl alcohol $| \text{Pt}$; N. Sasaki and K. Nakamura, $\text{Pt} | \text{KI}, \text{FeCl}_3, \text{NaCl} | \text{KCl} | \text{N-KCl}, \text{Hg}_2\text{Cl}_2 | \text{Hg}$; and W. D. Bancroft, $\text{Pt} | \text{FeCl}_3 | \text{Solution} | \text{Pt}$, where the "solutions" employed were KCl, Cl ; KBr, Br ; KOH, Cl ; KOH, Br ; KI, I ; $\text{KClO}_3, \text{H}_2\text{SO}_4$; $\text{KClO}_4, \text{H}_2\text{SO}_4$; $\text{KIO}_3, \text{H}_2\text{SO}_4$; NaSO_3 ; NaHSO_3 ; $\text{KNO}_2, \text{H}_2\text{SO}_4$; HNO_3 ; $\text{KMnO}_4, \text{H}_2\text{SO}_4$; MnO_2, HCl ; $\text{H}_2\text{Cr}_2\text{O}_7$; and $\text{K}_2\text{Cr}_2\text{O}_7$.

H. N. Warren observed that if bromine and a conc. soln. of ferric chloride be used in place of the dichromate in the dichromate cell, the e.m.f. is greater. L. Kahlenberg found that with a cell $\text{Pt} | A | C | \text{Pt}$, where A represents a soln. of 1.4508 grms. of FeCl_3 in 77.6 c.c. of nitrobenzene, and C , a 0.375*N*- FeCl_3 soln. in ethyl alcohol, the e.m.f. is 0.792 volt at 20°; and with the cell $\text{Pt} | B | C | \text{Pt}$, where B denotes a soln. of 0.1473 grms. of FeCl_3 in 10 c.c. of *o*-nitrotoluene, the e.m.f. is 0.623 volt. G. Tammann and E. Jenckel observed that in the cell $\text{Pd}(\text{H}_2) | 0.1N\text{-HCl}, \text{FeCl}_3 | 0.1N\text{-HCl}, \text{Hg}_2\text{Cl}_2 | \text{Hg}$, at 18°, when the ferric chloride soln. is under a press., p kgrms. per sq. cm., the e.m.f., E volts, is:

p	1	100	500	1000	1500	2000	2500	3000
E	0.4910	0.4901	0.4867	0.4831	0.4794	0.4759	472.4	0.4690
$dE/p \times 10^3$		-9.0	-8.6	-7.9	-7.7	-7.6	-7.4	-7.3

G. E. Gibson and W. A. Noyes found the **spark potential** in the vapour of ferric chloride is greater than it is in air. J. A. Fleming and J. Dewar found the **dielectric constant** (vacuum unity) for a sat. soln. of frozen ferric chloride at -198.8°, -162.7°, -144.9°, and -133.8° to be respectively 3.34, 3.56, 3.91, and 4.23. O. Milicka and A. Slama, and R. Fürth measured the dielectric constant of soln. of the salt.

According to M. Faraday, anhydrous ferric chloride is paramagnetic and, added C. Matteucci, neither the hexahydrate nor the anhydrous salt shows remanent magnetism. G. Wiedemann found that the **magnetism** of anhydrous ferric chloride is rather greater than is that of ferrous chloride with an equivalent proportion of iron, and is but little different from the value for the salt in aq. soln. A. Heydweiller observed that the equivalent magnetism of ferric chloride is scarcely any greater when in soln. than when it is in the form of the hexahydrate; the ratio is 1.006 : 1. E. Feytis gave for the molecular **magnetic susceptibility**, $14,652 \times 10^{-6}$ at 13°, and for the magnetic susceptibility $\chi = 102.5 \times 10^{-6}$ mass unit; G. Meslin gave $\chi = 102.5 \times 10^{-6}$; and T. Ishiwara, $\chi = 93.4 \times 10^{-6}$. T. Ishiwara's values for temp. below 44.6°, and K. Honda and T. Ishiwara's values for higher temp., in fields of about 2000 gauss, are:

	-170.4°	-147.0°	-62.5°	-3.7°	20°	69.7°	134.8°	191.9°	261.3°
$\chi \times 10^6$	252.0	195.5	121.0	94.5	86.2	73.8	60.9	50.4	35.6

The decrease from -190° to 200° is approximately in accord with $\chi T = \text{constant}$, but at higher temp. there are deviations which are attributed to the disturbing effects of sublimation, or the formation of an oxychloride. H. R. Woltjer and E. C. Wiersma found that the sp. susceptibility of the anhydrous salt depends on the absolute temp., T , in the formula $\chi(T - \theta) = \text{constant}$, down to -210°. The inversion temp., or Curie point, is $\theta = -252.6^\circ$. Above -180°, the susceptibility is independent of the intensity of the magnetic field. Anomalies occur at the temp. of liquid hydrogen, for the susceptibility then becomes independent of the intensity of the magnetic field, and the relation with temp. is the opposite to what it is at higher temp. H. Mosler found that the temp. coeff. of the susceptibility between 0° and 40° is 0.00326, a value a little greater than that of the hydrated salt. G. Berndt gave for the magnetic susceptibility $\chi = 47.5 \times 10^{-6}$ mass unit, and for the hexahydrate, 76.1×10^{-6} . L. A. Welo measured the temp. coeff. of the susceptibility, the magnetic susceptibility, and the Curie point of the liquid and solid hexahydrate. The results are plotted in Fig. 580. In the formula $\chi(T - \theta) = \text{constant}$, Curie's constant for the solid is 4.82, and for the liquid,

FIG. 580.—The Magnetic Susceptibility of Hydrated Ferric Salts — Molten and Solid.

3.79; whilst the Curie point, or the inversion temp., θ , is -36° for the solid, and 34° for the liquid. G. Berndt observed that the hysteresis of the hexahydrate in a field of 200 to 400 gauss cannot be detected.

M. Faraday observed that conc. aq. soln. of ferric chloride are paramagnetic. L. K  lp showed that a glass tube filled with the aq. soln. which has been magnetized in a definite direction for a long time requires for magnetization in the opposite direction less magnetism than before. This, said S. Henrichsen, does not mean that the soln. has a remanent magnetism, because the phenomenon is exhibited by evacuated tubes. C. Matteucci could detect no remanent magnetism; and L. Lombardi, no hysteresis, although P. Drapier observed a slight effect. J. Pl  cker found that strongly paramagnetic soln. on the poles of a strong magnet exhibit changes on the surface of the liquid. The subject was studied by P. Drapier, H. R. Woltjer and E. C. Wiersma, C. Marangoni, and A. Quartaroli. C. Stasescu observed changes in the conc. of a conc. soln. of ferric chloride near a strongly magnetic pole; and the phenomenon was studied by L. Abonnene, G. Falckenberg, P. Drapier, F. Ehrenhaft and E. Wasser, J. Jamin, J. Pl  cker, A. Quartaroli, W. Rathert, A. Righi, and W. Voigt and C. Stasescu. P. W. Selwood observed a slow decrease in the paramagnetism of the soln. on exposure to light. G. J  ger and S. Meyer found that the magnetic susceptibility of an aq. soln. of ferric chloride is $\chi = 73 \times 10^{-6}$ mass unit at 18° ; J. S. E. Townsend gave 92×10^{-6} at 10° ; G. Quincke, 91×10^{-6} at 19° ; O. Liebknecht and A. P. Wills, 83×10^{-6} at 18° ; J. K  nigsberger, 88×10^{-6} at 18° , and 92×10^{-6} at 21° ; and G. Falckenberg, 87×10^{-6} at 15° . Observations were also made by A. Arndtsen, H. Becquerel, H. E. J. G. du Bois, J. Borgmann, H. W. Eaton, A. von Ettinghausen, G. G. Gerosa and G. Finzi, S. Henrichsen, A. Lallemand, L. Lombardi, P. Pascal, G. Piaggese, J. Pl  cker, S. Prakash, A. Quartaroli, J. Schuhmeister, P. Siloff, T. W  hner, and G. Wiedemann. According to B. Cabrera and E. Moles, the sp. susceptibility χ mass units, and the molecular susceptibility, χ mol mass units, at temp. between 18.37° and 19.95° , are:

FeCl ₃ .	0.2105	0.4162	0.8247	0.2351 per cent.
$\chi \times 10^6$.	-0.5545	-0.3865	-0.0541	0.2924
$\chi_{\text{mol.}} \times 10^6$.	12,700	13,000	13,130	13,260
FeCl ₃ .	2.3864	4.8260	9.0710	14.8630 per cent.
$\chi \times 10^6$.	1.3022	3.4670	7.2547	12.440
$\chi_{\text{mol.}} \times 10^6$.	13,700	14,050	14,210	14,310

For soln. of ferric chloride with [HCl] mol of HCl per mol of FeCl₃, at 18.62° to 21.12° :

FeCl ₃ .	0.8431	0.8610	0.8221	0.8007 per cent.
[HCl] .	1.54	0.480	1.224	6.923
$\chi \times 10^6$.	-0.01288	0.04832	0.02781	0.012340
$\chi_{\text{mol.}} \times 10^6$.	13,540	14,410	14,740	14,780
FeCl ₃ .	3.3060	0.3046	0.32290	0.3119 per cent.
[HCl] .	0.0294	0.1521	0.3116	1.6120
$\chi \times 10^6$.	2.1448	2.2618	2.2393	2.2227
$\chi_{\text{mol.}} \times 10^6$.	13,990	14,580	14,790	15,210

The vol. susceptibility was also measured by A. Quartaroli; and the mol. susceptibility by A. Heydweiller, G. Falckenberg, P. Pascal, and A. Quartaroli. B. Cabrera and E. Moles noticed that the addition of hydrochloric acid drives back the hydrolysis, and raises the susceptibility. A. Quartaroli found the susceptibility is independent of the age of the soln., although the electrical conductivity, colour, and turbidity change. G. Wiedemann observed that the mol. magnetism decreases slowly as conc. soln. are diluted in consequence of hydrolysis; and if hydrochloric acid be added, the mol. magnetism is raised. A. Quartaroli found for soln. of *C* grms. of FeCl₃ in 100 c.c. of methyl alcohol, between 17° and 22° , for field-strengths of *H* gauss, the mol. susceptibility $\chi_{\text{mol.}}$ mass units:

$\text{FeCl}_3(C)$	2.135	4.271	4.271	16.85	25.39	25.39	50.78	101.56
H	32,000	32,000	32,000	14,100	14,100	9,700	9,700	9,700
$\chi_{\text{mol.}} \times 10^6$	14,789	16,066	16,098	17,883	18,846	19,058	19,064	18,479

Observations were also made by G. Quincke, R. Blondlot, and T. Wöhner on soln. in methyl alcohol; by M. Faraday, G. Wiedemann, A. E. Oxley, and J. S. E. Townsend, in ethyl alcohol. A. Quartaroli found for soln. with C grms. of FeCl_3 in 100 c.c. of ethyl alcohol, between 17° and 22° :

$\text{FeCl}_3(C)$	1.843	3.986	7.972	15.945	15.945	31.89	63.78	127.56
H	32,000	32,000	18,400	18,400	9,000	9,000	9,000	9,000
$\chi_{\text{mol.}} \times 10^6$	14,748	16,175	16,848	18,643	18,853	18,708	16,836	16,544

Similarly with soln. in isobutyl alcohol:

FeCl_3	4.411	8.223	8.223	16.647	16.647	31.295	70.59	
H	25,000	25,000	17,000	17,000	11,400	9,600	9,600	
$\chi_{\text{mol.}} \times 10^6$	17,064	17,038	17,203	17,200	17,392	17,592	16,992	

with isoamyl alcohol:

FeCl_3	4.12	8.24	16.48	32.96	32.96	65.92	131.84	
H	25,000	25,000	11,700	11,700	8,600	8,600	8,600	
$\chi_{\text{mol.}} \times 10^6$	16,092	16,298	17,855	18,364	18,687	17,252	17,395	

with allyl alcohol:

FeCl_3	4.062	8.123	16.25	16.25	32.50	65.00	130.00	
H	23,300	23,300	23,000	6,000	6,000	6,000	6,000	
$\chi_{\text{mol.}} \times 10^6$	15,940	16,110	17,541	18,045	17,608	17,525	17,333	

with ethyl ether:

FeCl_3	2.262	4.255	9.15	18.30	18.30	36.60	73.20	
H	25,000	25,000	25,000	15,500	8,200	8,200	8,200	
$\chi_{\text{mol.}} \times 10^6$	17,878	19,183	18,697	18,222	18,679	17,343	16,282	

Observations were also made by G. Wiedemann, and P. Drapier. A. Quartaroli found for soln. in acetone:

FeCl_3	1.786	3.573	3.573	14.293	28.587	28.587	51.175	114.35
H	32,000	32,000	25,000	11,800	11,800	7,200	7,200	7,200
$\chi_{\text{mol.}} \times 10^6$	14,795	15,606	15,707	18,009	16,878	17,574	17,073	16,271

with soln. in formic acid:

FeCl_3	6.67	13.34	26.68	26.68	53.37	53.37	106.74	
H	25,000	25,000	18,400	10,000	10,000	7,500	7,500	
$\chi_{\text{mol.}} \times 10^6$	1,528	15,736	16,576	16,696	16,599	17,408	17,598	

with soln. in acetic acid:

FeCl_3	3.035	3.035	6.07	12.14	24.28	48.56	48.56	97.12
H	32,000	25,000	25,000	25,000	12,000	12,000	9,200	9,200
$\chi_{\text{mol.}} \times 10^6$	17,397	17,387	17,485	16,905	18,204	17,364	17,509	17,017

with a soln. of 6.870 grms. of paramagnetic ferric chloride in a litre of diamagnetic methyl acetate, A. Quartaroli observed that the soln. is magnetically inactive; and with ethyl acetate:

FeCl_3	2.327	4.658	4.658	9.716	38.867	38.867	77.735	155.47
H	32,000	32,000	25,000	25,000	10,000	6,000	6,000	6,000
$\chi_{\text{mol.}} \times 10^6$	14,700	15,733	15,764	16,250	18,357	18,395	17,740	16,695

The magnetic rotation of soln. of ferric salts was studied by H. E. J. G. du Bois, H. Becquerel, M. E. Verdet, G. Quincke, A. Cotton, C. E. Richards and R. W. Roberts, and C. V. Raman and S. W. Chinchalkar. G. Wiedemann found that the *temperature coefficient* of the magnetization is smaller with soln. of ferric chloride which are hydrolyzed, than is the case with acidified soln. which are not hydrolyzed. The temp. coeff. of a 30 per cent. soln., between 10.45° and 60.8° , was found by P. Plessner to be 0.003542; G. Jäger and S. Meyer observed that the coeff. ranges between 0.0022 and 0.0029 for 6 to 42 per cent. soln. between 0° and 90° ; G. Piaggese gave 0.00277, 0.00283, and 0.00281 respectively for 12.86° , 21.14° ,

and 44.0 per cent. soln. between 24° and 85°. Observations were also made by A. E. Oxley, G. Quincke, J. S. E. Townsend, and R. H. Weber. H. Mosler's results are summarized in Fig. 581. The sp. magnetic susceptibility of the paramagnetic soln. was found by A. Quartaroli to increase with increasing concentration.

Fig. 581.—Temperature Coefficient of the Magnetic Susceptibility of Solutions of Ferric Chloride.

netically inactive with 6.875 grms. of FeCl_3 per litre of ethyl acetate; and with pyridine as solvent, with 14,160 grms. of FeCl_3 per litre. A. Heydweiller observed that the magnetic susceptibility is independent of the *field-strength* up to $H=40,000$ gauss; and this conclusion is in the main in agreement with the observations of A. Arndtsen, H. E. J. G. du Bois, H. W. Eaton, A. von Ettinghausen, H. Fahlenbrach, G. G. Gerosa and G. Finzi, S. Henrichsen, G. Jäger and S. Meyer, J. Königsberger, L. Lombardi, P. Philipp, P. Siloff, J. S. E. Townsend, T. Wähner, R. H. Weber, and O. Wylach. D. M. Bos and P. K. Raha noted that the paramagnetism decreased in light of a suitable wave-length.

K. Honda and T. Ishiwara calculated the saturation value for the magnetization of a mol of FeCl_3 to be 32,070, and hence gave 5.23×10^{23} for the **magnetic moment** of the molecule. E. Feytis gave 28.83 for the **magneton number**, and values were also given by B. Cabrera and E. Moles, D. M. Bose, P. Weiss, P. Philipp, and A. Quartaroli. A. Huber discussed the theory of the paramagnetic molecule.

The chemical properties of ferric chloride.—According to F. Wöhler, when ferric chloride is heated in dry **hydrogen**, it is first reduced to ferrous chloride, and then to iron (*q.v.*). A. B. Bagdasarian also showed that the reduction proceeds $\text{FeCl}_3 \rightarrow \text{FeCl}_2 \rightarrow \text{Fe}$ —*vide supra*, ferrous chloride. F. Schmitz said that the metal is pulverulent if obtained at 300° to 400°, but E. Péligot, and W. Spring obtained crystals at a higher temp. A. B. Bagdasarian added that some reduction of the ferric chloride is perceptible at 100°. C. Brunner observed that if hydrogen be passed for 48 hrs. through a dil. aq. soln. of ferric chloride, in darkness, some ferrous chloride is formed; but J. A. Wanklyn and W. J. Cooper, and S. Cooke could not detect any reduction with a conc. soln. kept 48 hrs. in an atm. of hydrogen. F. C. Phillips observed no reduction at room temp., and only a very slight reduction when the soln. was kept at 100° for several hours. W. Ipatéeff and A. I. Kisseleff, and J. H. Weibel obtained a white, easily oxidizable precipitate, by the action of hydrogen at a high press. on a soln. of ferric chloride at 350°. According to F. O. Schmitt and co-workers, soln. of ferric salts are not affected by hydrogen simultaneously exposed to ultrasonic waves. Nascent hydrogen in acid soln.—zinc, iron, aluminium, magnesium, etc.—reduces soln. of ferric chloride to ferrous chloride; the reduction also occurs in neutral soln., but in that case some hydrated ferric oxide is formed. A. C. Cumming and H. Smith showed that an excess of acid retards the reaction. According to D. J. Carnegie, the reduction does not depend on nascent hydrogen because it occurs with ease in absolute alcohol, and it is entirely independent of occluded hydrogen in the zinc. The argument is not conclusive. A. C. Chapman reported that hydrogen occluded in palladium rapidly reduces a soln. of ferric to ferrous chloride; the palladium is not attacked, whilst palladium free from hydrogen is readily attacked by a soln. of ferric chloride. This reduction was discussed by D. J. Carnegie, W. Fresenius, T. Graham, A. Hoenig, H. Gall and W. Manchot, and L. Kritschewsky. D. J. Carnegie observed

that hydrogen occluded in platinum is inactive, and B. Neumann added that hydrogen does not reduce the soln. in the presence of platinum, although S. Cooke observed that the reduction proceeds rapidly and regularly, and H. Gall and W. Manchot found that a hydrochloric acid soln. of ferric chloride in the presence of platinum sponge is quantitatively reduced at room temp.; and A. Pickles, that the soln. is rapidly reduced by hydrogen in the presence of fine copper gauze. W. Biltz and F. Meyer gave $\text{FeCl}_3.\text{Aq.} + \frac{1}{2}\text{H}_2 = \text{FeCl}_2.\text{Aq.} + \text{HCl.Aq.} + 16.0 \text{ Cals.}$ The reaction was also studied by H. Wolfram, and K. Jellinek and co-workers. W. Biltz and W. Holverscheid gave for the thermal value of the reaction: $\text{FeCl}_3.\text{Aq.} + \frac{1}{2}\text{H}_2 = \text{FeCl}_2.\text{Aq.} + \text{HCl.Aq.} + 10.3 \text{ Cals.}$ S. Reich and H. O. Serpek said that when **calcium hydride** is added to an ethereal soln. of ferric chloride, hydrogen is evolved and a brown precipitate, $\text{Ca}_3\text{FeCl}_5(\text{C}_4\text{H}_{10}\text{O})_3$, is formed.

J. L. Gay Lussac, and A. S. Miller observed that the crystals of anhydrous ferric chloride are very deliquescent when exposed to **air**, forming, according to M. Kinast, and B. Sandrock, pale orange-yellow crystals of the hemipentahydrate. P. Nicolardot added that when the crystals of ferric chloride are exposed to air for a long time at ordinary temp., some hydrochloric acid is given off, and a dirty yellow hydrolysis product remains. C. F. Mohr observed that the hexahydrate is hygroscopic, and J. Fritzsche observed that when exposed to dry air, the salt becomes darker in colour, with an apparent deliquescence, which was found by J. J. Berzelius, and H. Lescœur to be attended by a loss and not a gain of water. H. W. B. Roozeboom said that the hexahydrate can be kept a long time in air without change, but it is hygroscopic, and deliquesces in air when the vap. press. of water exceeds 6 mm. H. W. Hake made some observations on the subject. H. W. B. Roozeboom observed that the hemiheptahydrate is midway between the hexahydrate and the hemipentahydrate in its tendency to deliquesce in air; the hemipentahydrate is stable over conc. sulphuric acid at room temp. J. Fritzsche said that the hemipentahydrate is very deliquescent, and, added F. A. Flücker, it is much more deliquescent than the hexahydrate.

J. L. Gay Lussac observed that when ferric chloride is heated in **oxygen**, chlorine and ferric oxide are formed; and K. Hachmeister added that a similar reaction occurs when the salt is heated in air. H. Schulze found that in oxygen, the reaction begins at dull redness, and that a large proportion of the ferric chloride sublimes unchanged; hence, added G. F. Hüttig and H. Garside, the reaction in dry oxygen is not quantitative. E. W. Wescott added that the vapour of ferric chloride at 700° to 800° is rapidly and completely transformed by air or oxygen into chlorine and ferric oxide. E. W. Wescott obtained ferric oxide and chlorine by burning a spray of ferric chloride in air or oxygen at 800° . The blueing of tincture of guaiacum or of potassium iodide and starch by active oxygen is catalyzed by ferric chloride, and M. J. Gramenitzky found that if the soln. of ferric chloride be boiled and then cooled, the blueing reaction is inhibited, and regenerated if the soln. be left to stand for some time. The effect is attributed to the lowering of the dissociation by heat. The blueing reaction was studied by A. Simon and K. Kötschau.

The solubility of ferric chloride in **water**; the hydrolysis of the salt in aq. soln.; and the alleged volatilization of iron chloride when the aq. soln. is evaporated have been previously discussed. The hydrolysis of the salt accounts for the evolution of more or less hydrochloric acid when the aq. soln. is evaporated. J. Personne said that a neutral soln. of ferric chloride of sp. gr. 1.26 loses some chlorine when it is boiled, and this the more as the soln. becomes more concentrated. R. Stumper showed that the presence of ferric chloride has no appreciable effect on the rate of distillation of water. C. St. Pierre observed that when a dil. soln. acidified with hydrochloric acid is boiled, ferric chloride is not reduced to ferrous chloride, but J. C. Hostetter and H. S. Roberts observed that some reduction occurs when a 10 per cent. soln. is boiled for a short time. M. Schneider could detect no reduction when a conc. and strongly acidified soln. is exposed for a month in

darkness at 20°, but at 100°, some salt was reduced in the course of 12 hrs. J. M. Eder could detect no reduction when the solid salt or the aq. soln. is exposed to light, although H. Hérissé said that some reduction occurs in a soln. exposed to daylight for a long time. F. Kohn also said that the soln. undergoes a slow, very incomplete reduction when it is exposed to light; and M. Schneider added that at 20°, the rate of reduction is augmented by increasing the period of illumination, and by increasing the conc. of the soln. The reduction is not due to the presence of dust, but rather to the photochemical reaction $2\text{Fe}^{+++} + 2\text{Cl}^- \rightleftharpoons 2\text{Fe}^{++} + \text{Cl}_2$. R. Audubert, and K. Niederstadt also observed that a reduction occurs in ultra-violet light—*vide supra*. J. L. Gay Lussac observed that when ferric chloride is heated in steam, ferric oxide (hæmatite) and hydrogen chloride are formed. The reaction was studied by A. Daubrée, and E. Puxeddu. P. Nicolardot observed a similar reaction when the hydrated salt is heated.

F. K. Cameron and W. O. Robinson agitated for 3 months an excess of freshly precipitated hydrated ferric oxide with a soln. of ferric chloride, at 25°, and found the solid phases to be those indicated in Table XCII. The composition of the

TABLE XCII.—EQUILIBRIUM OF SOLUTIONS IN THE SYSTEM: $\text{Fe}_2\text{O}_3\text{--HCl--H}_2\text{O}$ at 25°.

Grms. per 100 grms. sat. soln.		Solid phase	Sp. gr.	Grms. per 100 grms. sat. soln.		Solid phase
Fe_2O_3	HCl			Fe_2O_3	HCl	
34.61	59.88	$\text{FeCl}_3 \cdot \text{HCl} \cdot 2\text{H}_2\text{O}$	1.485	21.84	29.33	$\text{FeCl}_3 \cdot 6\text{H}_2\text{O} +$
32.78	54.71	$\text{FeCl}_3 \cdot \text{HCl} \cdot 2\text{H}_2\text{O} +$	1.349	16.82	22.55	$\text{Fe}_2\text{O}_3 \cdot n\text{HCl} \cdot m\text{H}_2\text{O}$
31.95	58.20	$\text{FeCl}_3 + \text{FeCl}_3 \cdot 2\text{H}_2\text{O}$	1.284	14.62	19.53	"
34.42	54.12	$\text{FeCl}_3 \cdot 2\text{H}_2\text{O}$	1.242	10.56	13.76	"
34.21	55.47	$\text{FeCl}_3 \cdot 2\text{H}_2\text{O} +$	1.195	8.60	11.24	"
34.44	51.11	$\text{FeCl}_3 \cdot 3\frac{1}{2}\text{H}_2\text{O} + \text{FeCl}_3 \cdot 2\frac{1}{2}\text{H}_2\text{O}$	1.158	8.60	11.24	"
33.04	46.72	$\text{FeCl}_3 \cdot 3\frac{1}{2}\text{H}_2\text{O} + \text{FeCl}_3 \cdot 6\text{H}_2\text{O}$	1.070	4.04	5.36	"
24.42	33.42	$\text{FeCl}_3 \cdot 6\text{H}_2\text{O}$	1.047	2.85	3.66	"

solids in equilibrium with soln. with hydrochloric acid ranging from 3.66 to 30.20 per cent., and ferric oxide from 2.85 to 21.84 per cent., were of varying composition and gave no indication of the formation of a definite **ferric oxychloride** at 25°. The stable solid phase is one of a series of solid soln. containing ferric oxide, hydrochloric acid, and water. The solubility of freshly precipitated hydrated ferric oxide in soln. of ferric chloride led R. Phillips, J. M. Ordway, and others to assume that a soluble ferric oxychloride is formed. M. Pettenkofer thought that $\text{Fe}_2\text{Cl}_6 \cdot 5\text{Fe}_2\text{O}_3$ is formed; J. Jeannel, $\text{Fe}_2\text{Cl}_6 \cdot 9\text{Fe}_2\text{O}_3$; and A. Béchamp, $\text{Fe}_2\text{Cl}_6 \cdot 12\text{Fe}_2\text{O}_3$. G. C. Wittstein exposed a soln. of ferrous chloride in air and obtained a precipitate approximating $\text{Fe}_2\text{Cl}_6 \cdot 6\text{Fe}_2\text{O}_3 \cdot 9\text{H}_2\text{O}$ when dried at 50°; and A. Béchamp evaporated at 100° a soln. of ferrous chloride, and gradually added nitric acid and obtained a yellow precipitate, a similar precipitate approximated, when dried at 100°, $2\text{Fe}_2\text{Cl}_6 \cdot 25\text{Fe}_2\text{O}_3 \cdot 41\text{H}_2\text{O}$. This was obtained by boiling for a long time a soln. of ferric chloride in ten times its weight of water. When A. Béchamp's product was treated with water, $\text{Fe}_2\text{Cl}_6 \cdot 17\text{Fe}_2\text{O}_3$ was formed; and with aq. ammonia, $\text{Fe}_2\text{Cl}_6 \cdot 72\text{Fe}_2\text{O}_3$. These products are obviously stages in the hydrolysis of ferric chloride, and there is nothing to show that an indefinitely large number of analogous products would not be obtained by arresting the hydrolysis at different stages of its progress. The subject was also discussed by D. Tommasi, J. Böhm, P. Nicolardot, F. W. C. Krecke, and H. W. Fischer, and also in connection with the hydrosols of ferric oxide.

G. Rousseau heated a mixture of ferric chloride with 10 to 20 per cent. of water in bombs along with lime to remove the hydrogen chloride, and observed that at 150° to 220°, the product of the reaction is $2\text{Fe}_2\text{O}_3 \cdot \text{Fe}_2\text{Cl}_6 \cdot 3\text{H}_2\text{O}$, or the *hemihydrate*

of ferric oxychloride, $\text{FeOHCl} \cdot \frac{1}{2}\text{H}_2\text{O}$, which appears in doubly refracting, reddish-brown crystals, soluble in dil. acids, and passing into goethite when boiled for 100 to 150 hrs. with water. If the water acts on the ferric chloride at 220° to 280° , the anhydrous chloride, FeOCl , is formed; and at 300° to 340° , the complex $3\text{Fe}_2\text{O}_3 \cdot \text{Fe}_2\text{Cl}_6$, was said to be produced. The higher the temp. of the reaction, the smaller is the yield of the oxychloride. The reaction at a high temp. may thus involve (i) $\text{Fe}_2\text{Cl}_6 + 3\text{H}_2\text{O} = \text{Fe}_2\text{O}_3 + 6\text{HCl}$; (ii) $\text{Fe}_2\text{Cl}_6 + 2\text{H}_2\text{O} = 2\text{FeOCl} + 4\text{HCl}$; (iii) $(n+1)\text{Fe}_2\text{Cl}_6 + 3n\text{H}_2\text{O} = n\text{Fe}_2\text{O}_3 \cdot \text{Fe}_2\text{Cl}_6 + 6n\text{HCl}$; and (iv) $\text{Fe}_2\text{Cl}_6 + 6\text{H}_2\text{O} = 2\text{Fe}(\text{OH})_3 + 6\text{HCl}$; as well as (v) $\text{Fe}_2\text{Cl}_6 = 2\text{FeCl}_2 + \text{Cl}_2$; and (vi) $\text{Fe}_2\text{Cl}_6 = 2\text{FeCl}_3$. The action of heat on ferric chloride alone has been previously discussed. E. Stirnemann studied the action of steam on ferric chloride at high temp., and verified G. Rousseau's observations on the formation of the oxychloride by heating in a steel bomb, 35 to 45 grms. of ferric chloride with 1 to 1.5 grms. of water; after being heated for 1 to 2 hrs., the bomb was cooled in running water. The rhombic plates vary from pale to dark brown, according to their thickness, and those prepared at 450° to 480° have a deep violet lustre. The sp. gr. is 3.1. The crystals become deep violet at 450° to 480° . E. Wedekind and W. Albrecht gave $\chi = 35 \times 10^{-6}$ for the magnetic susceptibility. The dried salt can be kept in air for a long time, but in the moist state, there is hydrolysis: $6\text{FeOCl} + 6\text{H}_2\text{O} = 4\text{Fe}(\text{OH})_3 + \text{Fe}_2\text{Cl}_6$; and the moist salt in a few days is completely limonitized. At about 200° , in air, a mixture of ferric oxide and hydroxide is formed. When the dry salt is heated in a sealed tube at 350° , the vapour of ferric chloride appears; and similarly at 450° , when the greyish-black residue consists of hexagonal plates of hæmatite, so that the reaction is: $6\text{FeOCl} = 2\text{Fe}_2\text{O}_3 + \text{Fe}_2\text{Cl}_6$. N. Costachescu and G. Spacu studied the complex with pyridine, $\text{FeOCl}_2 \cdot \text{C}_5\text{H}_5\text{N}$; and K. A. Hofmann and G. Bugge, the complexes with ethyl carbylamine, $\text{Fe}_2\text{OCl}_4 \cdot 4\text{C}_3\text{H}_5\text{N}$, and $\text{Fe}_2\text{OCl}_4 \cdot 5\text{C}_3\text{H}_5\text{N}$.

E. Stirnemann studied the equilibrium conditions for the ternary system: Fe_2Cl_6 - FeOCl - Fe_2O_3 , and the results for the press. and temp. variations are summarized in Fig. 582. *A*, *B*, and *C* represent quadruple points: *A*, at about

FIG. 582.—Equilibrium Diagrams of the System: Fe_2Cl_6 - H_2O -Phases.

110° , and 5×10^{-8} atm., refers to $\text{Fe}_2\text{Cl}_{6\text{solid}}$, FeOCl , Fe_2O_3 , and gas; *B*, at 305° and 0.81 atm., refers to $\text{Fe}_2\text{Cl}_{6\text{solid}}$, $\text{FeOCl}_{\text{solid}}$, melt, and gas; whilst *C*, at 525° and 11.7 atm., refers to $\text{FeOCl}_{\text{solid}}$, Fe_2O_3 , solid, melt, and gas. Rising from these three points are the almost vertical curves representing the effect of press.; for *A*, $dt/dp = 0.05$ atm. (nearly). There is the curve of the vap. press. of ferric chloride over the oxychloride; the boiling curve of ferric chloride in the presence of the oxychloride, and the sublimation curve of ferric chloride in the presence of the oxychloride. Within the area *ABC* the system is bivariant, with the solid phase FeOCl , and to the right of the curve *AC*, the system is also bivariant with the solid phase Fe_2O_3 . The curve *AB* represents univariant systems, with the solid phases $\text{Fe}_2\text{Cl}_{6\text{solid}}$ and FeOCl ; curve *BC* likewise, but with molten ferric chloride

and the solid oxychloride, whilst curve *AC* likewise, but with the solids Fe_2O_3 and FeOCl .

There are three conditions of equilibrium: $\text{Fe}_2\text{Cl}_6 + 3\text{H}_2\text{O} = \text{Fe}_2\text{O}_3 + 6\text{HCl}$ for which $K_1[\text{HCl}]^6 = [\text{H}_2\text{O}]^3[\text{Fe}_2\text{Cl}_6]$, where the bracketed symbols refer to partial press., similarly for $\text{Fe}_2\text{Cl}_6 + 2\text{H}_2\text{O} = 2\text{FeOCl} + 4\text{HCl}$, where $K_2[\text{HCl}]^4 = [\text{H}_2\text{O}]^2[\text{Fe}_2\text{Cl}_6]$; and for $2\text{FeOCl} + \text{H}_2\text{O} = \text{Fe}_2\text{O}_3 + 2\text{HCl}$, where $K_3[\text{HCl}]^2 = [\text{H}_2\text{O}]$. E. Stirnemann studied the second of these systems and obtained for K_2 , 4.40×10^{-3} at 274° or 547°K. , but the results at 292° were not satisfactory. Applying the standard equation $\log K_2 - \log K_2 = (Q_2/R)(T_1^{-1} - T_2^{-1})$, where $Q_2 = 5400$ cal., K_2 is 4.40×10^{-3} at 294° , and 2.08×10^{-2} at 525° 798°K. It also follows from known data, that $K_1 = 8.77$ at 525° , when $Q_1 = -4500$ cal.; and $K_3 = 3.93 \times 10^{-2}$ when $Q_3 = -9900$ cal. The relative proportions of the solid phases at different temp. are indicated in the diagram, Fig. 583. The subject was also discussed by E. Baur.

FIG. 583.—Solid Phases in the System: $\text{FeCl}_3\text{--H}_2\text{O}$.

R. B. Smith and P. M. Giesy obtained a continuous curve in the electrometric titration of soln. of ferric chloride with sodium hydroxide, and inferred that no oxychlorides are formed. S. Goldsztaub found the space-lattice has $a = 3.75 \text{ \AA.}$, $b = 7.95 \text{ \AA.}$, and $c = 3.3 \text{ \AA.}$; and there are two mols. per unit cell. There are two layers of Cl-atoms, with two each of alternate Fe- and O-atoms, corresponding with the perfect cleavage parallel to (010).

For the action of **hydrogen dioxide**, *vide* the iron peroxides. V. L. Bohnson represented the reaction: (i) $2\text{FeCl}_3 + 3\text{H}_2\text{O}_2 + 2\text{H}_2\text{O} \rightleftharpoons 2\text{H}_2\text{FeO}_4 + 6\text{HCl}$; (ii) $2\text{H}_2\text{FeO}_4 + 3\text{H}_2\text{O}_2 \rightleftharpoons 2\text{Fe}(\text{OH})_3 + 2\text{H}_2\text{O} + 3\text{O}_2$; and (iii) $2\text{Fe}(\text{OH})_3 + 6\text{HCl} \rightleftharpoons 2\text{FeCl}_3 + 6\text{H}_2\text{O}$, where the second reaction is measurable, and furnishes constants for a unimolecular process. V. L. Bohnson and A. C. Robertson observed that a ferric acid, H_2FeO_4 , is probably formed as an intermediate product; that the temp. coeff. shows that the critical increment of the reaction is 23,960 cal., and that the frequency of the active radiation is 2.5×10^{14} when the wave-length is 1.2μ . E. I. Spitalsky and co-workers, I. S. Teletoff and co-workers, J. H. Walton and C. J. Christensen, W. Limanowsky, J. von Bertalan, J. Duclaux, C. S. Mummery, and A. von Kiss and F. E. Lederer also studied the reaction; and A. C. Robertson, the promotor action of cupric salts on the catalytic decomposition of hydrogen dioxide by ferric salts. H. Wieland and W. Franke studied the catalytic action of ferric salts on the decomposition of hydrogen peroxide, and found it to be less than with ferrous salts. G. Pellini and D. Meneghini observed that a well-cooled soln. of ferric chloride in anhydrous alcohol does not perceptibly influence chemically a 30 per cent. soln. of hydrogen dioxide; and the catalytic effect is very feeble. In alcoholic soln. of potassium hydroxide, and hydrogen dioxide, peroxides are formed. A. Brann, and J. H. Walton and D. O. Jones found that hydrogen dioxide reacts with an ethereal soln. of ferric chloride forming a precipitate; and with a quinoline soln. of ferric chloride, the hydrogen dioxide is vigorously decomposed. H. Kwasnik found that **barium dioxide** reacts with ferric chloride soln. in accord with $4\text{FeCl}_3 + 6\text{BaO}_2 + 6\text{H}_2\text{O} = 3\text{O}_2 + 4\text{Fe}(\text{OH})_3 + 6\text{BaCl}_2$.

O. Ruff, and O. Ruff and E. Ascher observed that when **fluorine** is passed over heated ferric chloride, ferric fluoride is formed. C. Friedel and J. M. Crafts said that the presence of **chlorine** hinders the dissociation of ferric chloride into ferrous chloride and chlorine at 440° , but W. Grünwald and V. Meyer observed no difference at 440° . K. H. Butler and D. McIntosh found that ferric chloride is insoluble in liquid chlorine; and J. Timmermans said that the solubility is less than 0.5 per cent. W. L. Goodwin observed that chlorine is less soluble in a soln. of ferric chloride than it is in water. M. C. Schuyten could detect no reaction between a

soln. of ferric chloride and **bromine** or **iodine**; but W. D. Bonner and H. Romeyn found that the ferric salts are reduced by iodides to the ferrous state. The reaction was studied by A. von Kiss and I. Bossanyi, and H. M. Dawson and E. Spivey. K. Schaum and W. Schleussner found that in the reaction between ferric ions and iodine the reversible photochemical reaction predominates over the Béquere effect. L. V. Pisarshevsky also studied the reaction: $\text{Fe}^{+++} + \text{I}^- = \text{Fe}^{++} + \text{I}$. J. Schröder observed that ferric chloride in pyridine soln. does not react with the halogens. The reaction was studied by M. Rosenberg. C. Poulenc found that gaseous **hydrogen fluoride** decomposes ferric chloride in the cold to form ferric fluoride; E. Petersen observed that **hydrofluoric acid** acts on a soln. of ferric chloride with the development of much heat. K. Fredenhagen found that ferric chloride does not dissolve in hydrofluoric acid. R. Schwarz and G. Meyer could not get dry or moist **hydrogen chloride** to unite with ferric chloride under press. and at a low temp., but hydrochloro-acids are formed when the hydrates of ferric chloride are similarly treated. R. Engel, and H. W. B. Roozeboom and F. A. H. Schreinemakers observed that when dry hydrogen chloride is passed over the hexahydrate, at ordinary temp., liquefaction occurs; and similar results were obtained with the hemiheptahydrate, the hemipentahydrate, and the dihydrate. The retardation of the hydrolysis of aq. soln. of ferric chloride by **hydrochloric acid** has been previously discussed. J. Schröder observed that ferric chloride in pyridine soln. does not react with the halide acids. The increase in the solubility of ferric chloride when hydrochloric acid is added to the soln. favours the assumption that complex hydrochloro-compounds are formed; F. G. Donnan and H. Bassett from these observations on the electrolysis of soln. of ferric chloride concluded that complex anions are formed in the hydrochloric acid soln.; E. Müller came to the same conclusion because ammonium thiocyanate does not give the characteristic red with soln. of ferric chloride in conc. hydrochloric acid; S. R. Carter and F. H. Clews, because of the fall in the oxidation potential of soln. of ferric chloride when hydrochloric acid is added; and S. R. Carter and N. J. L. Megson, because of the effect of hydrochloric acid and ferric chloride on the critical soln. temp. of isobutyric acid and water. H. W. B. Roozeboom and F. A. H. Schreinemakers' observations on the ternary system $\text{FeCl}_3\text{--HCl--H}_2\text{O}$ indicate the existence of ferric hydrotetrachloride, $\text{FeCl}_3\cdot\text{HCl}$, or HFeCl_4 , in the three hydrated forms di-, tetra-, and hexa-hydrates—*vide infra*; and R. Schwarz and G. Meyer's experiments on the dissociation press. show that there is a probability of the existence of **ferric hemitrihydrohemienneachloride**, $\text{FeCl}_3\cdot 1\cdot 5\text{HCl}\cdot 4\cdot 5\text{H}_2\text{O}$, as a green salt melting at -30° ; of **ferric dihydropentachloride**, $\text{FeCl}_3\cdot 2\text{HCl}\cdot 5\cdot 5\text{H}_2\text{O}$, as a pale green salt melting at about -35° ; of **ferric hemipentahydrohemihennachloride**, $\text{FeCl}_3\cdot 2\cdot 5\text{HCl}\cdot 6\text{H}_2\text{O}$, as a yellowish-green salt melting at -36° ; and of yellowish-green **ferric trihydrohexachloride**, $\text{FeCl}_3\cdot 3\text{HCl}\cdot 7\text{H}_2\text{O}$.

According to H. W. B. Roozeboom and F. A. H. Schreinemakers, the solubilities, *S* mols per 100 mols of water in soln. of hydrochloric acid, are

Solid phase: $\text{Fe}_2\text{Cl}_6\cdot 12\text{H}_2\text{O}$

P. Sabatier prepared **ferric hydrotetrachloride**, $\text{FeCl}_3 \cdot \text{HCl} \cdot 2\text{H}_2\text{O}$, or, according to A. Werner, $[\text{Fe}(\text{H}_2\text{O})_2\text{Cl}_4]$. The *dihydrate* was obtained by saturating hemipenta-

FIG. 584.—Phases in the Ternary System : FeCl_3 — HCl — H_2O .

$\text{Fe}_2\text{Cl}_6 \cdot 5\text{H}_2\text{O}$; IV, $\text{Fe}_2\text{Cl}_6 \cdot 4\text{H}_2\text{O}$; V, Fe_2Cl_6 ; VI, $\text{Fe}_2\text{Cl}_6 \cdot 2\text{HCl} \cdot 4\text{H}_2\text{O}$; VII, $\text{Fe}_2\text{Cl}_6 \cdot 2\text{HCl} \cdot 8\text{H}_2\text{O}$; VIII, $\text{Fe}_2\text{Cl}_6 \cdot 2\text{HCl} \cdot 12\text{H}_2\text{O}$; IX, H_2O ; X, $\text{HCl} \cdot 3\text{H}_2\text{O}$; XI, $\text{HCl} \cdot 2\text{H}_2\text{O}$; and XII, $\text{HCl} \cdot \text{H}_2\text{O}$. T. Nishimura and T. Toyama tried unsuccessfully to separate the isotopes of chlorine by converting the chlorine into hydrogen chloride, and then allowing that gas to act on hemiheptahydrated ferric chloride. The *tetrahydrate*, $\text{FeCl}_3 \cdot \text{HCl} \cdot 4\text{H}_2\text{O}$, or $\text{HFeCl}_4 \cdot 4\text{H}_2\text{O}$, was obtained by warming the hexahydrate, $\text{FeCl}_3 \cdot 6\text{H}_2\text{O}$, on a water-bath until it had lost two mols. of water,

and then passing hydrogen chloride over the product; and cooling the dark green liquid below -20° . The green, columnar crystals melt at -3° . The *hexahydrate*, $\text{FeCl}_3 \cdot \text{HCl} \cdot 6\text{H}_2\text{O}$, or $\text{HFeCl}_4 \cdot 6\text{H}_2\text{O}$, is obtained by passing hydrogen chloride over the hexahydrate, $\text{FeCl}_3 \cdot 6\text{H}_2\text{O}$, and cooling the liquid which is formed at -10° to -20° . The straw-yellow crystals melt at -6° . If the salt be kept at its m.p. for a long time, it forms the salt $\text{FeCl}_3 \cdot 6\text{H}_2\text{O}$. M. Bobtelsky studied the catalytic action of ferric chloride on the oxidation of hydrochloric acid by chromic acid.

Ferric chloride readily reacts with many **metal fluorides** forming complex fluorides which may be precipitated, or, if the ferric chloride be in excess, they may pass into soln. The subject was studied by J. Nicklès, R. Peters, A. Byk and H. Jaffe, J. Knobloch, and L. Szebelledy. Similarly, ferric chloride unites with many **metal chlorides** forming complex salts—*vide infra*. C. F. Schönbein observed that when a mixture of anhydrous ferric chloride and **potassium bromide** is heated, bromine is evolved and potassium and ferrous chlorides are formed. J. W. Retgers, R. Peters, and N. Sasaki observed that alkali bromides react with ferric chloride soln. forming orange-yellow or deep-brown ferric bromide. F. Krauss and T. von Heidelberg noted that with boiling, sat. soln., feebly acidified, **rubidium** and **cæsium bromides** give respectively **rubidium ferric chlorobromide**, and **cæsium ferric chlorobromide**. J. M. Eder discussed the action of ferric chloride on the **silver bromide** photographic plate. C. F. Schönbein found that, even in the cold, a mixture of anhydrous ferric chloride and **potassium iodide** gives off iodine forming potassium and ferrous chlorides, and the salt liberates iodine from solid potassium or ammonium iodide. P. Schulz, and A. Naumann and P. Schulz represented the reaction of ferric chloride in acetone soln. with a soln. of potassium iodide: $\text{FeCl}_3 + \text{KI} = \text{FeCl}_2 + \text{KCl} + \text{I}_2$, and $\text{FeCl}_2 + 2\text{KI} = \text{FeI}_2 + 2\text{KCl}$. D. J. Carnegie observed that ferric chloride reacts with potassium iodide in accord with $2\text{FeCl}_3 + 2\text{KI} = 2\text{FeCl}_2 + 2\text{KCl} + \text{I}_2$. The reaction was studied by E. I. Orloff, L. V. Pisarshevsky, H. Tominaga and S. Toraishi, N. Sasaki, A. von Kiss, A. von Kiss and I. Bossanyi, and K. Seubert and co-workers, and they suggest that an intermediate **ferric dichloroiodide**, FeCl_2I , may be formed: $2\text{FeCl}_2(\text{Cl}) + 2\text{KI} = 2\text{FeCl}_2\text{I} + 2\text{KCl}$, followed by $2\text{FeCl}_2\text{I} = 2\text{FeCl}_2 + \text{I}_2$. The photochemical reduction was studied by S. F. Ravitz and R. G. Dickinson. The complex **potassium ferric difluotrichloride**, $2\text{KF} \cdot \text{FeCl}_3$, reported by P. Guyot, could not be prepared by A. Greeff. According to M. J. Gramenitzky, the oxidation of guaiacum, and the liberation of iodine from potassium iodide, by ferric chloride are much delayed if the ferric chloride soln. has been recently boiled; when kept, the cooled soln. gradually regains its original oxidizing activity. The effect may be due to diminution of the dissociated ferric chloride molecules on boiling—*vide infra*, ferrous iodide. A. Jürgens observed that the reaction between **silver iodide** and a soln. of ferric chloride is not quantitative; some iodine is liberated. A. Engelhardt represented the reaction with **lead iodide**: $\text{PbI}_2 + 2\text{FeCl}_3 = \text{PbCl}_2 + 2\text{FeCl}_2 + \text{I}_2$. N. M. Bell found that aq. soln. of ferric chloride decompose **bleaching powder**; with conc. soln.—*e.g.*, 0.1N-FeCl_3 —chlorine is given off, and with more dil. soln., oxygen. Ferrates may also be formed. H. Schulze found that molten **potassium chlorate** reacts vigorously with ferric chloride forming ferric oxide. M. Herschkowitsch found that when a mixture of potassium chlorate and ferric chloride is moistened, heat is developed and chlorine and chlorine dioxide are produced.

A. Vogel observed that **sulphur** does not form iron sulphide when it is heated with ferric chloride. J. B. Cammerer found that when a 3 per cent. soln. of ferric chloride is boiled with finely-divided sulphur, some gas is evolved, and about 5 per cent. of the ferric chloride is reduced; and W. Wardlaw and F. H. Clews found that when a 5 to 8 per cent. soln. of ferric chloride in hydrochloric acid is boiled with colloidal sulphur, a little sulphuric acid is formed and only about 1 per cent. of the salt is reduced. According to A. W. Ralston and J. A. Wilkinson, ferric chloride forms a yellow soln. with liquid **hydrogen sulphide**, the soln. is not stable

since a chemical reaction sets in resulting in the formation of a white precipitate. The reaction is very fast at room temp. The sp. conductivity of a sat. soln., at the temp. of the ether-carbon dioxide mixture, is 209.9×10^{-6} mho. J. Durocher observed that the vapour of ferric chloride reacts with hydrogen sulphide producing iron disulphide. As shown by H. Rose, and H. W. F. Wackenroder, hydrogen sulphide reduces ferric salts to ferrous salts with the deposition of sulphur, and even in the cold some sulphuric acid is formed. The reaction was studied by E. Mischke. W. Moldenhauer and E. Mischke observed that in neutral or feebly acid soln., the speed of the reduction of ferric salts by hydrogen sulphide is too large to be measured, but it is measurable in the presence of hydrochloric, sulphuric or phosphoric acid. In sulphuric acid, at 0° and 20° , and in hydrochloric, at 0° , it is a termolecular reaction. In hydrochloric and phosphoric acid soln., at 20° , it is a bimolecular reaction. In all cases, the velocity diminishes rapidly with an increase in the conc. of acid, the velocity constant being a logarithmic function of the normality of the acid. The inhibiting influence of phosphoric acid on the rate of reaction is very much greater than that of either of the other acids, and when these are added to the former they influence the velocity only to a slight extent. The inhibiting action of acids is attributed to the formation of a complex compound the nature of which also influences the order of the reaction. The precipitate of iron sulphide formed in feebly acid, neutral, or slightly alkaline soln. contains only ferrous iron, thus suggesting that the reduction proceeds with even greater rapidity than precipitation. By the action of hydrogen sulphide on freshly-precipitated ferric hydroxide, or of strongly ammoniacal ammonium sulphide on ferric sulphate soln., exactly two-thirds of the iron appears to be reduced to the ferrous state. This is probably accounted for by the formation of a **ferrous sulphoferrite**, $4\text{FeS}, \text{Fe}_2\text{S}_3$. A. Wassermann studied the effect of ferric chloride as catalyst on the oxidation of hydrogen sulphide by hydrogen dioxide. **Alkali sulphides** or **hydrosulphides** precipitate black iron sulphide—*vide supra*, the chemical reactions of iron. P. Schulz, and A. Naumann and P. Schulz observed that ferric chloride in acetone soln. is partially reduced by hydrogen sulphide with the separation of sulphur. J. Schröder observed that hydrogen sulphide does not act on ferric chloride in pyridine soln.; A. Schier, that with a soln. in acetonitrile, sulphur but no sulphide is precipitated; and E. Busch observed an incomplete reaction in methylal soln. P. T. Walden found that liquid **sulphur dioxide** forms a yellowish-brown soln. with anhydrous ferric chloride; which gives a deep blood-red colour with ammonium thiocyanate, and a violet-brown with salicylic acid. H. P. Cady and R. Taft observed that the ferric salt is slowly reduced to ferrous salt; and on electrolysis, a black deposit appears on the cathode, and a red one on the anode; some gas is also developed on the anode. F. Ephraim and J. Kornblum observed no sulphur dioxide gas is adsorbed by anhydrous ferric chloride. Aq. soln. of the salt are reduced to ferrous salts by sulphur dioxide, or by **alkali sulphides** or **hydrosulphites** in the presence of a little free acid; if the soln. be alkaline to litmus, the reaction is slow. J. Pinnow found that a low H^+ -ion concentration favours the reduction of ferric chloride by sodium sulphite—*vide* 10. 57, 16. The reaction was studied by P. T. Austen and G. B. Hurff, T. W. Hogg, R. W. Atkinson, B. Glasmann, and A. C. Cumming and E. W. Hamilton. J. Schröder observed that sulphur dioxide does not act on ferric chloride in pyridine soln. O. Ruff and H. Einbeck found that **sulphur tetrachloride** forms **ferric sulphoheptachloride**, $\text{FeCl}_3.\text{SCl}_4$, in contact with ferric chloride; and the complex salt is very sensitive towards heat and moisture. According to E. Beckmann, ferric chloride dissolves in **sulphuryl chloride** to form a greenish-yellow soln. P. T. Walden found the mol. conductivity of soln. with a mol of ferric chloride in 125, 250, and 375 litres to be respectively 1.74, 2.31, and 3.01 at 25° . H. B. North and A. M. Hageman found that ferric chloride is readily soluble in heated **thionyl chloride**. J. Timmermans observed that ferric chloride is not soluble in **sulphur trioxide**. A. Vogel said that **sulphuric acid** produces a frothing when it acts on

ferric chloride, and hydrogen chloride is evolved: A. W. Davidson, and H. Friedrich observed that with 100 per cent. acid, yellowish-white ferric sulphate is formed. The reaction is slow in the cold, but rapid when the mixture is heated. M. Berthelot, and F. L. Browne and J. H. Mathews studied the heat developed on mixing dil. soln. of ferric chloride and dil. sulphuric acid. V. Macri found that ferric chloride soln. are instantly decolorized by dil. sulphuric acid and the colour is restored by sodium chloride. E. Pietsch and co-workers studied the reducing action of **sodium thiosulphate** on an ethereal soln. of ferric chloride; and H. Schmid, K. Jellinek and co-workers, J. Holluta and A. Martini studied the action of ferric chloride on an aq. soln. of sodium thiosulphate: $2\text{FeCl}_3 + 2\text{Na}_2\text{S}_2\text{O}_3 = 2\text{FeCl}_2 + 2\text{NaCl} + \text{Na}_2\text{S}_4\text{O}_6$; and J. Mika studied the reaction by electrometric titration. H. Debus observed that aq. soln. of **trithionates, tetrathionates, pentathionates, and hexathionates** are not perceptibly changed by soln. of ferric chloride.

C. Fabr  represented the reducing action of gaseous **hydrogen selenide** on soln. of ferric chloride at ordinary temp. by $\text{H}_2\text{Se} + 2\text{FeCl}_3.\text{Aq.} = \text{Se} + 2\text{FeCl}_2.\text{Aq.} + 2\text{HCl}.\text{Aq.} + 41.94 \text{ Cals.}$ C. R. Wise observed that 100 grms. of **selenium oxydichloride** dissolve 23.40 grms. of anhydrous ferric chloride, and ferric diselenium-dioxyheptachloride, $\text{FeCl}_3.2\text{SeOCl}_2$, is formed. A. P. Julien found the mol. conductivities of soln. with a mol. of ferric chloride in 1.372, 10.97, and 351.2 litres are respectively 3.164, 5.41, and 11.90 at 25° . The low value of the conductivity indicates that some complex salt is formed, and that no hydrolysis occurs. M. M. Smith and C. James observed that a precipitate is formed when **selenious acid** is added to a feebly acid soln. of ferric chloride, but if the soln. contains more than 5 per cent. of hydrochloric acid, no precipitation occurs. V. Lenher observed that **tellurium** reacts when heated with anhydrous ferric chloride in accord with $4\text{FeCl}_3 + \text{Te} = \text{TeCl}_4 + 4\text{FeCl}_2$; a similar reaction occurs in aq. soln. where the reaction is reversible. M. Berthelot and C. Fabr  represented the action of **hydrogen telluride** on a soln. of ferric chloride free from oxygen by $\text{H}_2\text{Te} + 2\text{FeCl}_3.\text{Aq.} = \text{Te} + 2\text{FeCl}_2.\text{Aq.} + 2\text{HCl}.\text{Aq.} + 58.24 \text{ Cals.}$ C. A. Tibbals found that **sodium telluride** reduces an acetic acid soln. of ferric chloride to ferrous chloride with the separation of some tellurium and the formation of tellurium tetrachloride. According to W. Pethybridge, and V. Lenher, a soln. of ferric chloride extracts tellurium from the **gold-silver telluride** ores: $(\text{Au}, \text{Ag})\text{Te}_2 + 8\text{FeCl}_3 = 2\text{TeCl}_4 + 8\text{FeCl}_2 + \text{Au}, \text{Ag}$. The reaction is slow in the cold, rapid when heated.

Ferric chloride is not attacked by **nitrogen**. A. Guntz found that **lithium nitride** acts so vigorously on ferric chloride that it is advisable to slow down the reaction by admixed sodium chloride. Some iron nitride is formed. A. Smits observed that with **magnesium nitride**, at a high temp., some iron nitride is formed, and decomposed at the high temp. of the reaction. F. Fichter and A. Spengel observed that **aluminium nitride** acts on a boiling, 4 per cent. aq. soln. of ferric chloride forming hydrated ferric oxide, and ammonium chloride equivalent to two-thirds the nitrogen. T. Curtius and J. Rissom obtained ferric azide by the action of **sodium azide** on a soln. of ferric chloride; and L. M. Dennis and A. W. Browne obtained a red coloration on adding **silver azide** to a pyridine soln. of ferric chloride. J. N. Br nsted and K. Volqvartz studied the catalysis of nitramide by ferric ions.

The tendency of the chloride to form complexes was studied by H. Hansen. H. Buff, A. W. F. Rogstadius, C. Stahlschmidt, and G. J. Fowler noticed that a nitride is formed when ammonia acts on ferric chloride at an elevated temp. According to H. Rose, and J. Persoz, ferric chloride slowly absorbs ammonia at ordinary temp. with the evolution of a small amount of heat, and the product approximates $\text{FeCl}_3 : \text{NH}_3$; but A. S. Miller showed that the reaction is vigorous, and much heat is developed so that if the current of ammonia be not conducted slowly at first, some salt may be decomposed, and ammonium chloride formed. The amount of gas absorbed at ordinary temp., say 18° to 23° , corresponds with the formation of **ferric hexamminochloride**, $\text{FeCl}_3.6\text{NH}_3$. This result was confirmed by

G. F. Hüttig. C. J. Gorter studied the subject. The action of ammonia on ferric chloride was also studied by O. T. Christensen. A. S. Miller obtained the hexammine as a reddish-brown powder by the direct action of ammonia on ferric chloride, and G. F. Hüttig recommended allowing the ammonia to act on ferric chloride for 2 hrs. at room temp., then 3 hrs. at -79° , and finally allowing the ammonia to escape at ordinary temp. and atm. press. The formation of the hexammine was found by F. Ephraim and S. Millmann to be attended by a great increase in volume. The yellowish powder was found by W. Biltz and E. Birk to have a sp. gr. of 1.54 at $25^{\circ}/4^{\circ}$. The hexammine is stable at room temp., in an atm. of ammonia, and when gently heated, but in a high vacuum it loses a mol. of ammonia at room temp.; A. S. Miller said that it forms a product approximating $3\text{FeCl}_3 \cdot 2\text{NH}_3$. F. Müller gave 36° to 115° for the dissociation temp. of the hexammine. The hexammine is insoluble in water, but H. Rose observed that his product was deliquescent in air, and dissolved in water with a hissing noise, and the formation of a dark red, transparent soln. F. Ephraim found the dissociation press. at 27.5° , 49° , 65° , and 70.5° to be respectively 112, 324, 586, and 714 mm. F. Müller gave 115° to 190° for the dissociation temp. of **ferric pentamminochloride**, $\text{FeCl}_3 \cdot 5\text{NH}_3$; 190° to 230° for that of **ferric triamminochloride**, $\text{FeCl}_3 \cdot 3\text{NH}_3$; and over 300° for the **ferric diamminochloride**, $\text{FeCl}_3 \cdot 2\text{NH}_3$. R. Samuel and A. R. R. Despande studied the absorption spectra of the complex chlorides. According to G. F. Hüttig, if the hexammine be placed in liquid ammonia at -79° , it forms **ferric dodecamminochloride**, $\text{FeCl}_3 \cdot 12\text{NH}_3$, whose dissociation press. at -79° is 9 mm. According to A. W. F. Rogstadius, and A. S. Miller, if ammonia acts on ferric chloride at a higher temp., reduction to ferrous chloride occurs, and ammonium chloride is formed. H. Buff, and C. Stahlschmidt found that at higher temp. some iron nitride may be formed. A. Forster and co-workers noted the formation of a precipitate when ammonia acts on an ethereal soln. of ferric chloride. P. Fireman observed that when **ammonium chloride** is melted with admixed ferric chloride a complex salt is formed, but at 400° to 420° , in a sealed tube, the reaction proceeds: $3\text{FeCl}_3 + \text{NH}_4\text{Cl} = 3\text{FeCl}_2 + 4\text{HCl} + \text{N}$. After 48 hrs' heating, about 95 per cent. of the theoretical yield of gas is developed. For the action of ammonia on the aq. soln. of ferric chloride, *vide infra*, the analytical reactions of iron salts. G. F. Hüttig and H. Garside passed dry ammonia into a soln. of ferric chloride in dry alcohol and obtained a yellow precipitate which rapidly darkens, and the soln. simultaneously deposits ammonium chloride. P. Schulz noticed that dry ammonia passed into an acetone soln. of ferric chloride gives a precipitate of ferric oxychloride and ammonium chloride, but no ammine is formed; an aq. soln. of ammonia precipitates hydrated ferric oxide which then dissolves in the excess of ferric chloride. J. Schröder observed that dry ammonia precipitates an insoluble complex salt from ferric chloride in pyridine soln.; E. Busch obtained a similar result with soln. in methylal. T. Curtius and F. Schrader, and H. Franzen and O. von Meyer obtained a brown precipitate on adding **hydrazine hydrate** to a soln. of ferric chloride; the precipitated **ferric hydrazine chloride** quickly passes into $\text{FeCl}_2 \cdot 2\text{N}_2\text{H}_4$. P. Purgotti represented the reaction with ferric salts: $5\text{N}_2\text{H}_4 + 4\text{Fe}_2\text{O}_3 = 8\text{FeO} + 4\text{NH}_3 + 3\text{N}_2 + 4\text{H}_2\text{O}$. A. Hantzsch and C. H. Desch observed that when **phenylhydrazine** is added to an ethereal soln. of ferric chloride, an addition product is precipitated without the evolution of a gas. L. Kahlenberg and A. T. Lincoln said that the soln. of ferric chloride in phenylhydrazine is not an electrical conductor. F. Haber showed that **hydroxylamine** oxidizes ferrous salts in alkaline soln. or in suspensions, and reduces ferric salts in acidic soln. He explained the phenomenon by assuming that hydroxylamine had two different structures, $\text{N}_3\text{N} : \text{O}$, and $\text{H}_2\text{N} \cdot \text{OH}$. A. D. Mitchell and co-workers studied the dynamics of the action of hydroxylamine on ferric salts and showed that the speed of the reaction after the early stages is directly proportional to the conc. of the hydroxylamine, to the square of that of the ferric chloride, and inversely proportional to the conc. of the ferrous salt, and to the square of the H^+ -ion conc. He assumes that the

reaction is complex: $2\text{Fe}^{++} + \text{NH}_2\text{OH} \rightleftharpoons \text{Fe}^{++} + 2\text{H}^+ + (\text{NOH}, \text{Fe}, \text{H})^{--} \rightarrow \text{N}_2\text{O}$, etc. The temp. coeff. of the reaction is 6.5 for 10° . The speed of the reaction is depressed by the addition of neutral salts. E. Ebler and E. Schott found that with a 5 per cent. soln. of hydroxylamine in a soln. of ferric chloride in absolute alcohol, at -18° , a brown precipitate containing hydroxylamine is deposited—probably **ferric hydroxylaminochloride**. R. Weber observed that **nitric oxide** acts on ferric chloride, and A. Besson obtained two products—a yellow powder at a low temp., and a brown product at a high temp. V. Thomas showed that with dry ferric chloride and dry nitric oxide, **ferric heminitrosylchloride**, $2\text{FeCl}_3 \cdot \text{NO}$, is formed as a yellowish-brown powder; if the temp. approaches 60° , dark red **ferric tetranitrosylchloride**, $4\text{FeCl}_3 \cdot \text{NO}$, is formed—*vide* 8. 49, 35. W. Manchot studied soln. of nitric oxide in alcoholic soln. of ferric chloride. A. Besson observed that at room temp., ferric chloride absorbs **nitrogen peroxide** gas, forming a compound which, according to V. Thomas, is **ferric nitroxylchloride**, $\text{FeCl}_3 \cdot \text{NO}_2$. At a higher temp., ferric oxide is formed. P. F. Frankland and R. C. Farmer found that the dry salt is insoluble in and not attacked by liquid nitrogen peroxide, but if traces of moisture be present, the salt is rapidly attacked and dissolved. V. Thomas, and I. Bellucci studied the action of nitric oxide on an ethereal soln. of ferric chloride, and found that ferrous chloride is formed; if some water be also present, the reaction is symbolized: $3\text{Fe}^{++} + \text{NO} + 2\text{H}_2\text{O} \rightleftharpoons 3\text{Fe}^{++} + \text{NO}_3' + 4\text{H}^+$. W. Manchot found that nitric oxide partially reduces the ferric chloride in soln. in acetone to ferrous chloride. R. Weber observed that if ferric chloride be warmed in the vapour of **nitrosyl chloride**, a complex salt is formed; H. Rheinboldt and R. Wasserfuhr observed that the clear, dark red liquid formed by the action of dry nitrosyl chloride vapour on dry ferric chloride at room temp., furnishes **ferric nitrosyl tetrachloride**, $\text{FeCl}_3 \cdot \text{NOCl}$, when the excess of nitrosyl chloride is evaporated off. The complex salt was studied by R. Weber, J. J. Sudborough, H. Gall and H. Mengdehl, and W. J. van Heteren. Dry ferric chloride was found by W. J. van Heteren to be soluble in liquid nitrosyl chloride forming ferric nitrosyl tetrachloride. I. Pesci represented the reaction of **potassium nitrite** on a soln. of ferric chloride by the equation: $2\text{FeCl}_3 + 6\text{KNO}_2 + 2\text{H}_2\text{O} = 2\text{FeO}(\text{OH}) + 6\text{KCl} + 2\text{HNO}_3 + 4\text{NO}$; and J. Matuschek, the reaction with **sodium nitrite** by $2\text{FeCl}_3 + 6\text{NaNO}_2 = 2\text{Fe}(\text{NO}_2)_3 + 6\text{NaCl}$, followed by $2\text{Fe}(\text{NO}_2)_3 + 3\text{H}_2\text{O} = 2\text{Fe}(\text{OH})_3 + 3\text{NO}_2 + 3\text{NO}$; he also found that a suspension of the hexahydrate in carbon disulphide reacts with sodium nitrite forming nitric oxide which escapes, and nitrogen peroxide which dissolves in the carbon disulphide. H. Wurtz observed that the repeated evaporation of a soln. of ferric chloride with **nitric acid**, mixed with a little potassium chlorate, ultimately yields ferric nitrate free from chlorine. V. Macri found that the soln. is decolorized by dil. nitric acid, and that the colour is restored by sodium chloride.

J. H. Gladstone observed that **phosphorus** acts on anhydrous ferric chloride forming phosphorus trichloride; and A. Granger added that at a dull red-heat, iron phosphide, Fe_2P_3 , is formed. L. Rosenstein found that red phosphorus when boiled with an acidified soln. of ferric chloride rapidly reduces it quantitatively to ferrous chloride. H. Rose found that when **phosphine** acts on dry ferric chloride in the cold, hydrogen chloride is evolved and iron phosphide is formed; and P. Kulisch showed that in aq. soln., phosphoric acid and ferrous chloride are produced. R. Weber, and A. E. Baudrimont found that **phosphorus pentachloride** reacts with ferric chloride furnishing dark brown **ferric phosphoctochloride**, $\text{FeCl}_3 \cdot \text{PCl}_5$, melting at about 98° , and boiling above 280° ; the salt is decomposed by water or moist air. A. W. Cronander studied this compound. P. T. Walden found that ferric chloride is slightly soluble in **phosphorus trichloride**—L. Kahlenberg and A. T. Lincoln said insoluble—and soluble in **phosphorus tribromide**, as well as in **phosphoryl chloride**. H. P. Cady and R. Taft said that the soln. in phosphoryl chloride becomes gelatinous in a few months; and when the soln. is electrolyzed, a black deposit appears on the cathode. G. Oddo said that soln. of 0.5307, 1.8426,

and 2.8633 grms. of ferric chloride in 100 grms. of phosphoryl chloride lower the f.p. respectively 0.575° , 0.942° , and 1.548° . O. Ruff and H. Einbeck obtained yellow, crystalline **ferric hemiphosphorylchloride**, $2\text{FeCl}_3 \cdot \text{POCl}_3$. C. Reinhardt observed that a warm soln. of ferric chloride is rapidly reduced by **sodium hypophosphite**; T. Salzer obtained a white precipitate on adding **hypophosphorous acid** to a soln. of ferric chloride; and C. Reinhardt found that a hydrochloric acid soln. of ferric chloride is decolorized by **phosphoric acid** owing to the formation of a ferric phosphate. V. Macri studied the action of phosphoric acid. E. Glatzel represented the reaction with **phosphorus pentasulphide**: $6\text{FeCl}_3 + 2\text{P}_2\text{S}_5 = 3\text{FeCl}_2 + 3\text{FeS}_2 + 4\text{PSCl}_3$.

According to J. Napier, H. Schild, and L. Kahlenberg and J. V. Steinle, **arsenic** dissolves in an aq. soln. of ferric chloride, and ferrous chloride is formed: $6\text{FeCl}_3 + 2\text{As} + 3\text{H}_2\text{O} = \text{As}_2\text{O}_3 + 6\text{FeCl}_2 + 6\text{HCl}$. P. Schulz said that arsenic does not act on ferric chloride in acetone soln., and J. Schröder observed that ferric chloride is reduced to ferrous chloride in pyridine soln. R. Napoli represented the action of **arsine** on a soln. of ferric chloride by $3\text{FeCl}_3 + \text{AsH}_3 = 3\text{FeCl}_2 + \text{AsCl}_3 + \frac{3}{2}\text{H}_2$, and the arsenic trichloride is hydrolyzed to arsenious acid. The reaction with arsine is slow in neutral soln., but more rapid in acidic soln., but it is not quantitative. H. Reckleben and co-workers said that the **arsenious acid** is oxidized to arsenic acid. C. F. Schönbein found that **arsenic trioxide** intensified the colour of a dil. aq. soln. of ferric chloride. L. Winogradoff, and K. Jellinek and L. Winogradoff observed that ferric chloride is reduced by **arsenious acid**: $2\text{FeCl}_3 + \text{H}_3\text{AsO}_3 + \text{H}_2\text{O} \rightleftharpoons 2\text{FeCl}_2 + \text{H}_3\text{AsO}_4 + 2\text{HCl}$ in the presence of 1.5*N*- to 4*N*-HCl, at 107° to 127° , in sealed tubes. At 107° , the constant $[\text{H}_3\text{AsO}_3] \cdot [\text{FeCl}_3]^2 / [\text{H}_3\text{AsO}_4] \cdot [\text{FeCl}_2]^2 \cdot [\text{HCl}]^2$ is 3.54×10^{-2} ; at 127° , it is 1.17×10^{-1} . The thermal value of the (\rightarrow) reaction is +18,000 cal. Both reactions appear to be termolecular, and are strongly catalyzed by hydrochloric acid. The kinetics of the reaction were studied by J. C. Sarma. P. T. Walden found that **arsenic trichloride** dissolves ferric chloride forming a yellow soln. which, according to L. Kahlenberg and A. T. Lincoln, is a good electrical conductor. P. T. Walden also found that ferric chloride is sparingly soluble in **arsenic tribromide**; the soln. with a mol of ferric chloride per 100 litres has a mol. conductivity of 1.325 at 33° ; the lowering of the f.p. of a 0.129 per cent. soln. is 0.170° . These results being different from what are obtained with soln. of other substances in this solvent are attributed to a chemical reaction between solvent and solute. T. Rieckher found that when **arsenic sulphide** is boiled with a soln. of ferric chloride, arsenic chloride is formed and volatilized quantitatively, and J. B. Cammerer represented the reaction with a 3 per cent. soln. of ferric chloride: $\text{As}_2\text{S}_3 + 10\text{FeCl}_3 + 5\text{H}_2\text{O} = \text{As}_2\text{O}_5 + 10\text{FeCl}_2 + 10\text{HCl} + 3\text{S}$, only traces of sulphuric acid and arsenious acid are formed. J. Napier observed that a hot, neutral or feebly acidic, conc. soln. of ferric chloride attacks **antimony**, forming ferrous and antimonous chlorides; and analogous results were obtained by J. Attfield, T. Rieckher, H. Schild, and N. Welwart. P. Schulz said that antimony slowly reduces ferric to ferrous chloride in acetone soln., and J. Schröder obtained a similar result in pyridine soln. S. Tolloczko found that ferric chloride forms a brown soln. with **antimony trichloride**. R. F. Weinland and H. Schmid obtained a complex with **antimony pentachloride**, namely, **antimony ferric octochloride**, $\text{SbCl}_5 \cdot \text{FeCl}_3 \cdot 8\text{H}_2\text{O}$. W. Lindner, and T. Rieckher found that powdered **antimony sulphide** is easily attacked by a boiling, feebly acidic soln. of ferric chloride: $6\text{FeCl}_3 + \text{Sb}_2\text{S}_3 = 6\text{FeCl}_2 + 2\text{SbCl}_3 + 3\text{S}$. J. B. Cammerer said that with a 3 per cent. soln. of ferric chloride some antimony oxychloride is formed. D. J. Carnegie added that antimony sulphide does not reduce ferric chloride soln. According to J. Napier, **bismuth** readily dissolves in a soln. of ferric chloride, with a quantitative reduction to ferrous chloride, and the formation of bismuth chloride: $\text{Bi} + 3\text{FeCl}_3 = \text{BiCl}_3 + 3\text{FeCl}_2$. H. Schild, A. Kurtenacker and F. Werner, and W. Strecker and A. Herrmann obtained confirmatory results; and P. Schulz said that bismuth slowly reduces ferric to ferrous

chloride in acetone soln., and J. Schröder obtained a similar result in pyridine soln. K. Someya observed that the reduction is quantitative with **bismuth amalgam**. J. Aloy studied the action of **bismuth trioxide**, on the soln. of ferric chloride. G. Herrmann observed that ferric chloride and **bismuth chloride** have a eutectic at 171.5° and 23 per cent. of ferric chloride, Fig. 585, but no compound is formed. J. B. Cammerer found that the reaction with **bismuth sulphide** resembles that with antimony sulphide.

According to C. F. Schönbein, and E. Heymann and co-workers, when a soln. of ferric chloride is shaken up with powdered **carbon**, it is reduced to ferrous chloride; the action is quicker the finer is the grain-size of the carbon. Wood charcoal and lamp-black act faster than sugar charcoal. Powdered coke acts similarly. Washing the powdered coke with hydrochloric acid and water was found by A. Tingle to reduce its activity. N. Schiloff and B. Nekrassoff studied this subject. V. S. Krym and S. J. Pantschenko, and G. Stadnikoff and N. F. Proskurnina examined the reducing action of coke, coal, anthracite, and lignite. The reaction is represented: $4\text{FeCl}_3 + 2\text{H}_2\text{O} + \text{C} = 4\text{FeCl}_2 + 4\text{HCl} + \text{CO}_2$. E. Heymann found the reducing value, expressed in milligram atoms of iron per gram of carbon or wood charcoal purified by hydrochloric acid and water, is 0.75, and when the charcoal is de-gassed at 800° in vacuo for 3 days, 1.48; Ceylon graphite washed with hydrochloric acid and water, and de-gassed at 300° , 0.007; Acheson graphite, similarly treated, 0.007; carbonized hæmoglobin heated 5 hrs. in vacuo at 800° , 0.79; and carbon obtained from carbon tetrachloride, 1.23 to 1.40. The adsorption of ferric chloride from aq. soln. by carbon was studied by A. Tingle, E. Heymann and co-workers, N. Schiloff and L. Lepin, H. Leunig, N. Schiloff, D. J. W. Kreulen, T. Sabalitschka and W. Erdmann, and A. W. Thomas and T. R. le Compte; and from its soln. in acetone, and ethyl acetate, by W. F. O. de Coninck. The reducing action of animal charcoal was studied by W. Heintz, W. F. O. de Coninck, and R. Kuhn and A. Wassermann. E. Baur and A. Rebmann studied the effect of ferric chloride on the photolysis of **carbon dioxide**; and W. Mang, the action of **thiocarbonates**. W. Manchot and co-workers found that soln. of 0, 13.433, and 21.558 grms. of FeCl_3 per 100 c.c. dissolve, respectively, 95.7, 63.0, and 51.6 c.c. of **acetylene** at 25° . L. Kahlenberg and A. T. Lincoln found that ferric chloride is soluble in **heptane**, **amylene**, **toluene**, **menthene**, **xylene**, and **cymene**, and that the soln. do not conduct the electric current. R. Schmalz said that ferric chloride is insoluble in **cyclohexane**. J. Timmermans observed that **benzoyl-p-xylene** dissolves less than 0.5 per cent. of ferric chloride. R. Colley, and E. Busch observed that ferric chloride is sparingly soluble in **benzene**, forming a yellow soln. which becomes brown. L. Kahlenberg and A. T. Lincoln said that the soln. is a poor electric conductor. J. Timmermans observed that ferric chloride is soluble in **ethylbenzene**, and in **naphthalene**.

The complex with **trimethylethylene** was studied by W. C. Gangloff and W. E. Henderson; with **stilbene**, and with **diphenylbutadiene**, by H. von Euler and H. Willstädt. M. C. Boswell and R. R. McLaughlin observed that in Friedel-Crafts' reaction, the presence of ferric chloride stimulates the catalytic action of aluminium chloride although ferric chloride alone has only one-third the activity of aluminium chloride—a subject studied by W. A. Riddell and C. R. Noller. J. Timmermans observed that the solubility of ferric chloride in **methyl chloride** is less than 0.5 per cent., likewise **methyl bromide**, and in **ethyl chloride** and **bromide**; it is soluble in **methylene chloride**; and **chloroform** dissolves over 0.5 per cent. FeCl_3 . E. Busch said that the soln. in chloroform is yellow which, with time, changes to brown. K. Ott studied the reaction between ferric chloride in chloroform soln. and benzyl sulphide. L. Kahlenberg and A. T. Lincoln observed

Fig. 585.—Freezing-point Curves of the Binary System: $\text{BiCl}_3\text{--FeCl}_3$.

that soln. of ferric chloride in chloroform, and **carbon tetrachloride** are non-conducting; J. Timmermans said that the salt is insoluble in carbon tetrachloride; and that **bromoform** dissolves over 0.5 per cent. FeCl_3 . K. Ott observed that the salt is soluble in **acetylene tetrachloride**, **ethylene trichloride**, and **ethylene dichloride**. L. Kahlenberg and A. T. Lincoln found that soln. of ferric chloride in **ethylene chloride** and **bromide** are non-conducting; likewise also are soln. in **methylene iodide**, in **trichlorobenzene**, in **bromobenzene**, in **benzyl chloride**, and in **benzal chloride**. Soln. of ferric chloride in **acetyl chloride** were found by L. Kahlenberg and A. T. Lincoln, and L. I. Shaw to be good conductors, likewise also soln. in **benzoyl chloride**, whilst soln. in **epichlorhydrin** are fair conductors. The complex salt with benzoyl chloride was studied by M. Nencki, and J. Boeseken. The complex with **phenyl bis-methylchloride** was studied by M. Gomberg and L. H. Cone; with **phenyl tris-methylchloride**, with **phenyl-bromotrismethyl chloride**, and with **phenyl-iodo-trismethylchloride**, by A. Bayer and H. Aickelin; **tri-*p*-tolylchloromethane**, by M. Gomberg; with the **phenylpyrylium chlorides**, by W. Dilthey; with the **benzopyrylium chlorides**, by H. Decker and co-workers, W. Dilthey, W. Borsche and K. Wunder, and W. H. Perkin and co-workers; with **naphthopyrylium chloride**, by H. Decker and co-workers, and R. Fosse and L. Lesage; with **xanthylium chlorides**, by H. Decker and co-workers, A. Werner, M. Gomberg and L. H. Cone, M. Gomberg and C. J. West, L. H. Cone and C. J. West, F. Kehrmann and J. Knop, and J. von Braun and E. Aust; with **coeroxonium chloride**, by H. Decker and co-workers; with **benzocoeroxonium chloride**, by E. Laube, and H. Decker and E. Laube; with **coerbioxonium chloride**, by H. Decker and co-workers; with **tribenzylsulphonium chloride**, and cyanide, by A. Forster and co-workers, and K. A. Hofmann and K. Ott; with **methylthioxanthylium chloride**, by H. Decker and co-workers; with **coerthonium chloride**, and **methylcoerthonium chloride**, by H. Decker and co-workers; with **coerbithonium chloride**, and **dimethylcoerbithonium chloride**, by H. Decker and co-workers; with **thianthrene-dithonium chloride** and **methoxythianthrenedithonium chloride**, by K. Fries and co-workers; and with various **phenazthonium chlorides**, by F. Kehrmann and L. Schild, R. Mitsugi and co-workers, and R. Möhlau and co-workers. Soln. in **methyl or ethyl sulphide** were found by J. Timmermans to dissolve more than 0.5 per cent. of FeCl_3 ; P. C. Ray and P. C. Mukherjee discussed complexes with ethyl sulphide, $\text{H}[\text{FeCl}_4(\text{C}_4\text{H}_{10}\text{S})(\text{H}_2\text{O})]$, and with methylene sulphide, $\text{HFeCl}_4(\text{C}_2\text{H}_4\text{S})_2 \cdot 4\text{H}_2\text{O}$. The complex with **benzyl sulphide** was studied by A. Forster and co-workers; with ***p*-tolylsulphoxide**, by K. A. Hofmann and K. Ott; and with **tribenzylphosphine oxide**, by F. Fleissner. A. Benrath observed a reaction with **trioxymethylene** occurs in benzene soln.

G. Gore said that a soln. of ferric chloride is not reduced by **carbon monoxide** admixed with the dioxide. A. Mittasch found that ferric chloride is almost insoluble in **nickel carbonyl**. J. Timmermans said that ferric chloride is insoluble in **carbon disulphide**; but H. Arctowsky, and E. Busch said that it forms a pale yellow soln. L. Klein, and H. Stolzenberg observed that anhydrous ferric chloride unites with **hydrogen cyanide** with a hissing noise, and then dissolves in an excess of the solvent. When the excess of solvent is evaporated, there remain brownish-red crystals of ferric dihydrocyanidochloride, $\text{FeCl}_3 \cdot 2\text{HCN}$. The complex was studied by L. Klein. L. Kahlenberg and H. Schlundt found the mol. conductivities of soln. with a mol of ferric chloride in 4.17, 33.12, 431.1, and 1042.0 litres of solvent to be respectively 111.7, 154.0, 213.7, and 259.9. Observations were also made by K. Fredenhagen and J. Dahmlos. E. Pietsch and co-workers studied the action of **potassium ferrocyanide** on ferric chloride in ethereal soln. L. Klein found that **cyanogen chloride** is taken up by ferric chloride with the evolution of heat. J. H. Gladstone, G. Magnanini, J. Clarens, and G. Krüss and H. Moraht studied the reversible reaction with **thiocyanates**: $\text{FeCl}_3 + 3\text{KCys} \rightleftharpoons \text{Fe}(\text{Cys})_3 + 3\text{KCl}$. A. K. Bhattacharya and N. R. Dhar found that the reaction with potassium thiocyanate is favoured by light of wave-length 8500 Å. K. C. Bailey observed

that in the extraction of soln. of potassium thiocyanate and ferric chloride with ether, in the case where the thiocyanate predominates, and where the colour is paler, the ether extracts practically pure thiocyanate, whilst when the ferric chloride is in excess and the soln. is sufficiently concentrated to impart some colour to the ether, hydrochloric acid formed by hydrolysis of ferric chloride liberates thiocyanic acid, and the extract contains both ferric chloride and thiocyanic acid. In H. Lachs and H. Friedenthal's process the extraction of small quantities of iron with ether becomes progressively more difficult as the proportion of iron in the soln. is reduced. K. C. Bailey and J. D. Kidd found the f.p. curve of potassium thiocyanate and ferric chloride does not have breaks indicative of the formation of complex salts. J. F. Durand and K. C. Bailey studied the reaction with silver thiocyanate. J. Clarens said that the thiocyanic acid liberated in acidic soln. does not react with ferric chloride but is slowly polymerized. E. Schaer observed that the reaction with thiocyanates is more sensitive in alcoholic than in aq. soln. J. Schröder obtained red colorations with silver and potassium thiocyanates and a pyridine soln. of ferric chloride; and with ammonium thiocyanate, ammonium chloride is also precipitated. A. Schier observed blood-red colorations are produced by thiocyanates in soln. of ferric chloride in acetonitrile. K. A. Hofmann and co-workers found that dry **ferrous cyanide** in a soln. of ferric chloride in dry alcohol gave a dark blue precipitate.

E. Lloyd and co-workers gave for the solubility of anhydrous ferric chloride in **methyl alcohol** at 0°, 15°, and 30°, respectively 1.31, 1.43, and 1.61. According to A. Benrath, ferric chloride in methyl alcohol soln. is rapidly reduced to ferrous chloride, on exposure to sunlight. The light supplies the energy necessary for the formation of aldehyde, etc., as products of primary reaction: $2\text{FeCl}_3 + \text{CH}_3\text{OH} = 2\text{FeCl}_2 + \text{H.CO.H} + 2\text{HCl}$, and $2\text{FeCl}_3 + \text{C}_2\text{H}_5\text{OH} = 2\text{FeCl}_2 + \text{CH}_3\text{CO.H} + 2\text{HCl}$; conc. soln. deposit crystals of $\text{FeCl}_2 \cdot 4\text{CH}_3\text{OH}$, and if any water is present crystals of $\text{FeCl}_2 \cdot 4\text{H}_2\text{O}$ are formed. Observations were also made by W. F. O. de Coninck. F. Kuhlmann examined the action of heat on the soln., and E. Lloyd and co-workers found that when the alcoholic soln. is warmed above 50° for a long time, chloroform and a red precipitate are produced; if the soln. is boiling, hydrogen chloride is evolved. Ferric chloride is soluble in **ethyl alcohol**; likewise also the hydrates, as observed by G. C. Wittstein; and, according to F. L. Winckler, the soln. in 96 per cent. alcohol remains liquid when cooled to -7.5°, but when stirred with a glass rod, the yellow liquid solidifies, and the temp. rises to 19°. W. Schnellbach and J. Rosin found that 100 grms. of ethyl alcohol dissolve 51.45 grms. of ferric chloride. M. Prasad and P. S. Limaye studied the photochemical reduction of the alcoholic soln. E. Lloyd and co-workers observed that **ferric diethylalcohol chloride**, $\text{FeCl}_3 \cdot 2\text{C}_2\text{H}_5\text{OH}$, is formed, and the domain of existence is indicated in Fig. 586. The solubility, *S* grms. of FeCl_3 per gram of dry alcohol, is:

	0°	15°	30°	40°	50°	40°	30°	20.6°	30°	40°
<i>S</i> . . .	1.36	1.41	1.49	1.55	1.76	1.87	1.94	1.99	2.03	2.07
	$\text{FeCl}_3 \cdot 2\text{C}_2\text{H}_5\text{OH}$							FeCl_3		

The results are plotted in Fig. 586; there is a eutectic at 20.6°; and the m.p. of the complex, $\text{FeCl}_3 \cdot 2\text{C}_2\text{H}_5\text{OH}$, is about 50°. The raising of the b.p. of the alcoholic soln. was found by P. T. Müller, and E. Beckmann to be in harmony with the assumption that the mol. of the solute is FeCl_3 . E. Lloyd and co-workers found that when the soln. is kept at a temp. over 50° for some time, chloroform and a red precipitate are formed as in the case of methyl alcohol; the boiling soln. gives off hydrogen chloride. H. J. H. Fenton, and J. H. Walton and C. J. Christensen studied the oxidation of alcohol by hydrogen dioxide with ferrous or ferric salts as catalysts. R. Phillips, W. F. O. de Coninck, and H. Mosler observed that a soln. of ferric chloride in ethyl alcohol is hydrolyzed with the separation of hydrated ferric oxide; the hydrolysis does not proceed so readily as in aq. soln. The tincture *tonico-nervina*, mentioned in connection with the history of the iron

chlorides, was a soln. of ferric chloride in alcohol, and it was known to the early chemists that the liquid was decolorized by exposure to light, and that the golden-yellow colour of the soln. was restored in darkness—but, according to T. von Grothuss, not completely. The reaction was studied by J. Fiedler, and G. Kerner.

FIG. 586.—The Solubility of Ferric Chloride in Ethyl Alcohol.

A. Benrath's observations on the action of light on the soln. are indicated in connection with soln. in methyl alcohol; the subject was also investigated by E. Puxeddu. Observations on the magnetic susceptibility, and electrical conductivity of soln. in methyl, ethyl, **isobutyl**, **isoamyl**, **allyl**, and **benzyl alcohols**, **glycol**, and **glycerol**, are indicated above. M. Prasad and N. V. Sohoni studied the photochemical decomposition of soln. in ethyl, propyl, butyl, and amyl alcohols. The physical and chemical properties of these soln. are also discussed above. L. Kahlenberg and

A. T. Lincoln observed that ferric chloride is soluble in **phenol**, and in *m*-**cresol**, and the soln. are electrically a conductor; the solubility in phenol was found by J. Timmermans to exceed 0.5 per cent., and likewise with **phenetol**, and **anethol**, whilst L. Kahlenberg and A. T. Lincoln observed that the soln. in **anisol** is electrically a conductor. The absorption spectra of soln. of ferric chloride and phenol were investigated by E. F. Wesp and W. R. Boode. T. Pavolini studied the action of the salt on **phenol oxide**; and J. V. Dubsky and co-workers, on **glycocoll**; and K. Kimura and H. Sueda, on **dimethylglyoxime**.

A. F. Gehlen said that anhydrous ferric chloride dissolves in **ether** with the evolution of heat; H. E. Williams, that the hexahydrate dissolves in dry ether; G. C. Wittstein, that the hemiheptahydrate dissolves in ether; and E. Pinerua, that it similarly dissolves in ether saturated with hydrogen chloride. J. W. Rothe observed that some of the ether is decomposed, and E. Busch noted that the soln. at first yellow soon becomes dark brown. When the ethereal soln. is evaporated, A. Forster and co-workers observed that ferric chloride is decomposed. E. Beckmann, P. T. Müller, and R. Lespieau studied the mol. wt. of the salt from the effect on the b.p. of ether, and found results in agreement with FeCl_3 for dil. soln., and in conc. soln. a partial polymerization to Fe_2Cl_6 . According to A. Vogel, ferric chloride is perceptibly volatile from an ethereal soln. even at temp. below 30° , but H. P. Talbot said that the volatility cannot be greater since the ether distilled from the soln. on a water-bath contains only traces of iron. This trace may have been mechanically carried over, and not the result of volatility—*vide supra*, the volatility of ferric chloride. F. Mylius and C. Huttner noted that the ethereal soln. suffers some decomposition at a higher temp. A. F. Gehlen observed that when an ethereal soln. of ferric chloride is decomposed by exposure to light, the ferric chloride is reduced to the ferrous salt; and observations on the subject were made by F. Jahn, A. Benrath, L. E. Jonas, and J. W. Rothe. P. Chastaing studied the relation between the rate of the reduction and the wave-length of the light—violet light is the most active, whilst yellow light and red light act very slowly. E. Puxeddu, and E. Puxeddu and F. L. Vodret found that the change occurs more slowly in arc-light than in sunlight, and they showed that some chlorine is consumed in chlorinating the ether so that the reaction is not reversible in the dark. Conc. ethereal soln. yield ferrous chloride and a black organic compound containing iron. Up to a certain stage of progress, the reaction appears unimolecular. One form of the *tinctura tonico-nervina*, mentioned above, was a soln. of ferric chloride in a mixture of alcohol and ether, and it was known to T. von Grothuss, E. L. Schubarth, G. Suckow, and A. F. Gehlen that it forms ferrous chloride on exposure to sunlight, and some ethyl chloride is produced at the same time. J. Fiedler studied the reaction. E. G. Thorin found that ether is less soluble in 0.5N- FeCl_3 than it is in water; and F. N. Speller that ether is less soluble in a hydrochloric acid soln. of ferric chloride than it is in aq. hydrochloric acid

alone. He found that *S* c.c. of ether are dissolved by 100 c.c. of aq. hydrochloric acid with ferric chloride in soln. at 16° to 19°:

Sp. gr. HCl	1-177	1-140	1-123	1-115	1-093	1-075	1-055
<i>S</i>	139	71-5	43-3	35	21-5	16	12

W. Skey proposed to separate ferric chloride from many associated chlorides by shaking the aq. soln. with ether. Two layers are formed—an ethereal soln. of ferric chloride, and an aq. soln. of other chlorides below. The process was examined by J. W. Rothe, M. Hanriot, and J. W. Mellor. F. Mylius and C. Hüttner, and N. de Kolossowsky studied the distribution of ferric chloride between water and ethyl ether at 18°; and F. N. Speller found that when a gram of iron as ferric chloride is dissolved in 100 c.c. of aqueous hydrochloric acid of different concentrations, at 18°, and shaken with 100 c.c. of ether, the distribution of the ferric chloride between the two layers is as follows:

Sp. gr. HCl	1-193	1-158	1-151	1-123	1-111	1-103	1-0825	1-06	1-0424
Fe ₂ { Aq.	99-0	92-84	74-0	7-2	2-0	1-95	10-0	87-0	99-6 per cent.
Ether	1-0	7-16	26-0	92-8	98-0	98-05	90-0	13-0	0-4 „

The complex with ethyl ether was studied by A. Forster and co-workers. R. Phillips observed that the presence of **sugar** in the aq. soln. hinders the hydrolysis of ferric chloride; and R. M. Purkayastha studied the reduction of ferric chloride by sugars. A. Dumansky and L. G. Krapiwina studied the ternary system: $\text{FeCl}_3\text{-H}_2\text{O-sugar}$. A. Benrath found that ferric chloride dissolves in **formaldehyde**, and the soln. is decomposed with the formation of ferrous chloride in light, and when heated. L. Kahlenberg and A. T. Lincoln noted that ferric chloride dissolves in **acetaldehyde** with the development of heat, and, according to A. Benrath, this liquid forms a black, spongy mass. C. Dufraisse and R. Horclois studied the catalytic action of ferric chloride on various organic compounds. L. Kahlenberg and A. T. Lincoln observed that ferric chloride is soluble in **chloral**, but the soln. is non-conducting; and it is also soluble in **paraldehyde**, and the soln. is a good electrical conductor, as observed by L. Kahlenberg and A. T. Lincoln—*vide supra*; the salt is soluble in **cinnamic aldehyde**, and the soln. is a fair electrical conductor. P. T. Walden found that **benzaldehyde** forms a brown soln. with ferric chloride, and observations on the electrical conductivity (*q.v.*) were made by P. T. Walden, and L. Kahlenberg and A. T. Lincoln. E. Raymond studied the catalytic oxidation. L. I. Shaw found the soln. of ferric chloride in **salicylaldehyde** is a good conductor (*q.v.*), and observations were made by L. Kahlenberg and A. T. Lincoln, and A. T. Lincoln. Similar observations were made with respect to soln. in **furfurol**. W. C. Gangloff and W. E. Henderson studied the complex with **furfuraldehyde**. W. Eidmann observed that ferric chloride is soluble in **acetone**; and P. Schulz, and A. Naumann and P. Schulz added that a gram of the FeCl_3 dissolves in 1-5888 grms. of acetone at 18°, and the sp. gr. is 1-1603. The soln. were studied by W. H. Krug and K. P. McElroy. J. Timmermans observed that the soln. decomposes on keeping and deposits a precipitate; P. Schulz added that with the purified acetone, much of the ferric chloride is reduced to ferrous chloride, but if the acetone be sat. with hydrogen chloride, no reduction occurs. W. F. O. de Coninck observed that a very dil. soln. is stable in light, but not so if traces of methyl alcohol are present. The soln. are rapidly decolorized when filtered through animal charcoal. The soln. with some methyl alcohol, unlike the soln. with purified acetone above, gives a precipitate with silver nitrate after filtration through the charcoal. This is the result of a partial decomposition of the acetone soln. containing the methyl alcohol. L. Kahlenberg and A. T. Lincoln, and A. T. Lincoln found that ferric chloride is soluble in **methylpropylketone**, and the soln. is electrically conducting (*q.v.*); likewise with soln. in **acetophenone**. J. Timmermans observed that **benzophenone** dissolves more than 0-5 per cent. of ferric chloride. The complex with benzophenone was studied by J. Boeseken; with **phenyl-cyclopentene**, by W. Borsche and W. Menz; with **dibenzalacetone**, by F. Straus, and A. Rosenheim and W. Levy;

with **cinnamylideneacetophenone**, and **dicinnamylideneacetone**, by A. Rosenheim and W. Levy; with **phenanthrenequinone**, by K. H. Meyer; with **2,4-dimethoxy-w-oxybenzalacetophenone**, by W. H. Perkin and co-workers; with **dimethylchromone** and **dimethylthiochromone**, by H. Simonis and A. Elias; and with **naphthodioxime**, and **naphthothioxime**, by B. Ghose and S. Smiles. G. Champetier represented the reaction of **phenyl magnesium bromide** on ferric chloride by the equations: (i) $6\text{C}_6\text{H}_5\text{MgBr} + 2\text{FeCl}_3 \rightarrow 3(\text{C}_6\text{H}_5)_2 + 2\text{Fe} + 3\text{MgBr}_2 + 3\text{MgCl}_2$; (ii) $2\text{C}_6\text{H}_5\text{MgBr} + 2\text{FeCl}_3 \rightarrow (\text{C}_6\text{H}_5)_2 + 2\text{FeCl}_2 + \text{MgBr}_2 + \text{MgCl}_2$; and (iii) $2\text{C}_6\text{H}_5\text{MgBr} + \text{FeCl}_2 \rightarrow \text{Fe} + \text{MgBr}_2 + \text{MgCl}_2$. E. Beckmann found that the salt is soluble in **benzil**. The complex with **urea** was studied by G. A. Barbieri; and with **tetra-phenylurea**, by R. H. Pickard and J. Kenyon. S. C. De and T. K. Chakravorty studied the action of ferric chloride and hydrogen dioxide on **thiosemicarbazones**.

A. Benrath found that ferric chloride dissolves in **formic acid**, and when the soln. is warmed, hydrogen chloride escapes, and on cooling, crystals of **ferric chloroformate**, $\text{FeCl}(\text{H.COO})_2 \cdot 0.5\text{H}_2\text{O}$, are deposited. A. Rosenheim and P. Müller studied this reaction; V. Macri, the decolorization of a soln. of ferric chloride by formic acid; A. Benrath, the decomposition of the soln. in sunlight with the evolution of carbon dioxide; and A. Quartaroli, the magnetic properties (*q.v.*) of the soln. J. Timmermans, and A. W. Davidson found that ferric chloride is soluble in **acetic acid**, and the soln. slowly deposits a reddish-brown precipitate. R. Weinland and co-workers studied the complex salts formed by the action of ferric chloride on acetic acid. A. Benrath observed that the soln. of ferric chloride in acetic acid is stable in light. A. Quartaroli studied the magnetic properties (*q.v.*) of the soln.; V. Macri, the action of acetic acid; and R. Weinland and A. Höhn, R. Weinland and H. Hachenburg, and R. Grünberg-Krasnowskaja, the complex chloroacetates. L. Kahlenberg and A. T. Lincoln observed that ferric chloride forms with **acetic anhydride** a soln. which is electrically a conductor. A. Benrath found that ferric chloride, or its hexahydrate, forms a dark brown soln. with **propionic acid**, and the soln. slowly deposits crystals of **ferrous chloropropionate**, $\text{FeCl}(\text{C}_2\text{H}_5\text{COO})$. R. Weinland and A. Höhn studied the complex salts with propionic acid. J. Timmermans observed that ferric chloride is insoluble in **stearic acid**. J. W. Döbereiner, J. M. Eder, and G. Lemoine showed that **oxalic acid** displaces most of the hydrochloric acid from ferric chloride, and that under the influence of light, the oxalic acid is oxidized to carbon dioxide. In darkness, the reaction begins at 50° , and increases in speed up to 100° . The reaction was studied by F. V. Jodin, A. Jodbauer, E. Baur, M. Roloff, J. Fiedler, M. Padoa, M. Padoa and N. Vita, A. J. Allmand and W. W. Webb, E. Menke, G. Kornfeld and E. Mencke, A. K. Sanyal and N. R. Dhar, A. Benrath and co-workers, E. Shpolsky, H. Kunz-Krause and P. Manicke, R. F. Weinland and F. W. Sierp, E. Marchand, A. J. Allmand and K. W. Young, and B. K. Mukerji and N. R. Dhar. Actinometers based on the reaction were devised by J. W. Draper, H. N. Draper, L. Warnerke, E. Marchand, G. Kornfeld and E. Mencke, A. Lipowitz, and T. Woods. J. C. Ghosh and R. M. Purkayastha, and R. M. Purkayastha studied the action of light on soln. of ferric chloride in **lactic**, **tartaric**, and **mandelic acids**; A. Benrath and K. Schaffganz, the photochemical reaction between tartaric acid and ferric chloride; S. Hakomori, the formation of complexes with tartaric acid; and J. C. Ghosh and B. N. Mitra, the extinction coeff. of soln. of ferric chloride in formic, acetic, propionic, oxalic, lactic, tartaric, mandelic, **malonic**, **succinic**, **glycollic**, and **citric acids**. C. V. Smythe found that a mixture of ferric chloride with lactic, glycollic, oxalic, tartaric, citric, or **malic acid**, is more acidic than is the case with the acid alone. This is explained by the formation of complexes and the hydroxylic ions. The reactions with citric and malic acids were studied by R. M. Purkayastha. The organic acid is oxidized by exposure to light. The results may be explained by supposing that there is an equilibrium in soln. between ferric chloride and acid as reactants and an intermediate complex formed by the loose combination of one mol. of each of the reactants, and by assuming a definite value of the molecular

extinction coeff., for each wave-length, for the intermediate complex so formed. V. Macri studied the action of tartaric acid. W. D. Treadwell and W. Fisch studied the complexes formed with **dicarboxylic acids**; and C. Morton, with **salicylic acid**. J. H. Walton and D. P. Graham studied the oxidation of the dicarboxylic acids with ferric chloride and hydrogen dioxide. The complex with **benzhydroxamic acid** was studied by R. Weinland and G. Baier; and with **cinnamic acid**, by A. Rosenheim and W. Levy.

P. C. Ray and P. C. Mukherjee obtained complex salts with **ethyl sulphide** and with **1:4-dithian**. L. I. Shaw found that ferric chloride is soluble in **dimethyl sulphate**. L. Kahlenberg and A. T. Lincoln, and A. T. Lincoln studied the electrical conductivity (*q.v.*) of soln. of ferric chloride in **amyl nitrite**; in **ethyl nitrate**—good conductor; in **ethyl chlorocarbonate**—good conductor; and **ethyl carbonate**—non-conductor; L. Kahlenberg, soln. in **methyl thiocyanate**, in **ethyl thiocyanate**, in **amyl thiocyanate**, and in **ethyl isothiocyanate**. L. Kahlenberg said that ferric chloride is soluble in **allyl isothiocyanate**. J. Rill, and A. Naumann and J. Rill observed that ferric chloride is soluble in **methyl acetate**, forming a yellow soln., which E. Busch said becomes deeper in colour and finally brown. A. Quartaroli studied the magnetic properties (*q.v.*). J. Allain le Canu, E. Alexander, A. Naumann and E. Alexander found that ferric chloride is soluble in **ethyl acetate**. The mol. refraction (*q.v.*) of the soln. was studied by J. H. Gladstone; the electrical conductivity (*q.v.*) by L. I. Shaw, and L. Kahlenberg and A. T. Lincoln; and the magnetic properties (*q.v.*) by A. Quartaroli. W. F. O. de Coninck observed that the yellow, dil. soln. is stable in light; and it is decolorized by filtration through animal charcoal. L. Kahlenberg and A. T. Lincoln, L. Kahlenberg, and E. Pietsch and co-workers studied the action of **sodium acetate** on ferric chloride in ethereal soln. W. D. Treadwell and W. Fisch studied the complexes formed with acetates. A. T. Lincoln observed the electrical conductivities of soln. of ferric chloride in **propyl acetate**—poor conductor; in **butyl acetate**—poor conductor; in **amyl butyrate** and **amyl valerianate**—poor conductors; and in **ethyl monochloroacetate**, **ethyl cyanoacetate**, **diethyl oxalate**, **ethyl acetoacetate**, and **ethyl benzoate**. L. Letellier studied the reaction with ethyl acetoacetate. The complex with **ethyl cinnamate** was studied by A. Rosenheim and W. Levy; and with **trimethyl thiophosphate**, by P. Pistschimuka. K. Charitschkoff said that **naphthenic acid** reduces ferric to ferrous chloride; and E. S. Hill studied iron as a catalyst in the oxidation of **dialuric acid**.

L. Kahlenberg and A. T. Lincoln found that ferric chloride dissolves in **nitrobenzene**, and the lowering of the f.p. indicates a decrease in the mol. wt. with increasing conc.; they also measured the electrical conductivity (*q.v.*) of the soln.; and L. Kahlenberg, the e.m.f. of cells with this soln. (*q.v.*). Similarly also with soln. of ferric chloride in **m-nitrotoluene**, and in **o-nitrotoluene**. F. L. Shinn found that a sat. soln. of ferric chloride in **ethylamine** has a sp. conductivity of 13.5×10^{-6} mho at 0°; and H. McKee Elsey said that a complex salt is formed. L. Kahlenberg, L. Kahlenberg and O. E. Ruhoff found that ferric chloride dissolves slowly in **amylamine**, and the soln. are electrically conducting (*q.v.*). J. Schröder, and A. Naumann and J. Schröder observed that the soln. of ferric chloride in **pyridine** is reddish-yellow, and probably contains a complex salt. A. Werner and W. Schmujloff studied the mol. raising of the b.p. The electrical conductivity—*vide supra*—was studied by L. Kahlenberg and A. T. Lincoln, and A. T. Lincoln; A. Quartaroli found that paramagnetic ferric chloride and diamagnetic pyridine give a magnetically inactive soln. with 14.160 grms. FeCl_3 per litre. J. Schröder observed that the reddish-yellow soln. becomes darker with time; and when heated in a sealed tube, F. Hein and W. Retter observed a condensation of the pyridine to $\alpha\alpha'$ -dipyridyl occurs. Water added to the soln. precipitates the iron as ferric hydroxide. The complex with pyridine was studied by G. Spacu, N. Costachescu and G. Spacu, R. F. Weinland and O. Schmid, and R. F. Weinland and A. Kissling; with $\alpha\alpha'$ -**dipyridyl**, by F. Blau; with **antipyrine**, by R. F. Weinland and O. Schmid,

L. A. Welo, F. Hasse, Knoll and Co., A. Astruc and J. Bouisson, and M. C. Schuyten ; and with **pyramidon**, by R. F. Weinland and O. Schmid ; E. Beckmann observed that ferric chloride is soluble in boiling **quinoline**, and L. Kahlenberg and A. T. Lincoln added that the soln. is electrically conducting. The complex with quinoline was studied by R. Weinland and co-workers ; and W. Franke studied the system ferric iron and **quinol**. E. F. Wesp and W. R. Brode studied the spectra of compounds of ferric chloride and **phenol**. J. Timmermans observed that **dipropylamine** dissolves less than 0.5 per cent. of ferric chloride ; and, added O. Stephani, the solvent and solute react chemically ; he also found that **aniline** dissolves over 0.5 per cent. of ferric chloride, and L. I. Shaw, and L. Kahlenberg and A. T. Lincoln said that the soln. is a poor conductor of electricity. A. Forster and co-workers observed that a compound is formed with aniline and ferric chloride in ethereal soln. Y. Osaka and co-workers studied the system : ferric chloride, water, and aniline at 25°. The complex with aniline was studied by A. R. Leeds, and J. L. C. Schröder van der Kolk ; with *p*-**nitrosodi-*n*-butylaniline**, by J. Reilly, and J. Reilly and W. J. Hickinbottom. J. Timmermans said that **piperidine** dissolves over 0.5 per cent. of ferric chloride, but L. Kahlenberg and A. T. Lincoln said that the salt is insoluble in piperidine, and in **xylydine**—both meta, and asymmetric ; the soln. in **monomethylaniline**, **dimethylaniline**, *o*-**toluidine**, *m*-**toluidine**, and in **benzylamine** are poor conductors. W. H. Patterson studied the action of ferric chloride on *o*-, *m*-, and *p*-toluidine. E. Busch, A. Schier, and A. Naumann and A. Schier observed that the soln. of ferric chloride in **acetonitrile** is blood-red when conc., and yellowish-red when dil. ; the presence of dry hydrogen chloride makes the soln. pale yellow. The complex with **hexamethylenetetramine** was studied by L. Vanino and A. Schinner, and J. C. Duff and E. J. Bills observed that with boiling soln., ferric hydroxide is precipitated. Complex salts with **benzidine** were studied by G. Spacu, and A. Simon and T. Reetz ; with **tetramethyldiaminotriphenylamine**, by W. Madelung and co-workers ; with **ethyl carbylamine**, and **phenylcarbylamine**, by K. A. Hofmann and G. Bugge. J. Kämmerer, and A. Naumann observed that yellow soln. are formed by ferric chloride in **benzonitrile**, and L. Kahlenberg and A. T. Lincoln, and L. I. Shaw found that soln. are good electric conductors. G. Kornfeld found that ferric chloride dissolves in **formamide** like it does in water. He measured the mol. lowering of the f.p., and observed that the soln. may be kept unchanged at 0°, but not at room temp. T. Murayasu found that the electrical conductivity of ferric chloride soln. is increased by the addition of **glycocoll**. W. Eidmann found that ferric chloride is soluble in dry **methylal**, and E. Busch added that at 18°, the sat. soln. contains 20.28 grms. FeCl₃ in 100 grms. of soln. He measured the mol. raising of the b.p. The dark green soln. does not decompose in daylight ; and it becomes reddish-brown when treated with a small proportion of water ; the soln. absorbs hydrogen chloride and becomes intensely green. The solubility of ferric chloride in methylal saturated with water at 18° is 47.35 grms. FeCl₃ per 100 grms. of soln. J. Timmermans found that **sulphonal** dissolves over 0.5 per cent. of ferric chloride ; T. Chakrabarti and S. De studied the action of ferric chloride on **thiocarbamides** ; G. Fuseya and K. Murata, and T. Murayasu studied the complexes formed by iron salts with **glycine** ; R. M. Purkayastha, with **sugars** ; and W. Franke, with **hydroquinone**. W. D. Bancroft and co-workers studied the photochemical reduction of soln. of ferric chloride in the presence of **organic dyes**. G. Klose observed that 100 grms. of **lanolin**, of m.p. 46°, dissolve 4.17 grms. of FeCl₃ at 45°. M. Scholtz observed the formation of complexes with many **alkaloids**. The action of ferric chloride on **albumin** was studied by H. Bechhold, G. Buchner, A. Brossa and H. Freundlich, H. J. M. Creighton, G. Grasser, E. Heymann and F. Oppenheimer, I. G. Oberhard, W. Pauli and L. Flecker, H. Schorn, and A. W. Thomas ; on **casein**, by H. Palme ; on **hæmoglobin**, by H. Freundlich and G. Lindau ; on **gelatin**, by H. J. M. Creighton, R. E. Liesegang, L. Cramer, and M. Schneider ; on **soap** soln., by P. Verbeck ; W. Thomson and F. Lewis, **indiarubber** ; T. Katsurai, **milk** ; and on **wool**, by N. Schiloff. The retarding influence

of gelatin on the hydrolysis of the aq. soln. of ferric chloride was observed by C. L. Wagner, A. Tian, N. R. Dhar and D. N. Chakravarti, and R. E. Liesegang; and on **cellulose**, by W. Kopaczewsky and M. Rosnowsky. The action of ferric chloride in the tanning of **animal skins** was described by J. Jettmar; in the classification of **sewage**, by L. H. Enslow, F. Fischer, and A. Gärtner; and in the precipitation of **bacteria**, by O. Schwarz.

H. Moissan said that **boron** reduces ferric chloride in aq. soln. to ferrous chloride; but P. Lebeau observed no reduction when finely-powdered **silicon** is boiled for a long time with a 10 per cent. soln.—nor is the silicon perceptibly attacked. H. Moissan and S. Smiles found that a soln. of ferric chloride is readily attacked by **silicoethane**. O. Hönigschmid and co-workers observed that at a high temp. **quartz** is attacked by anhydrous ferric chloride. A. Tian, and N. R. Dhar and D. N. Chakravarti discussed the action of silica gel on the soln. J. R. Glauber, G. J. Mulder, and E. Jordis and W. Hennis observed the formation of an "iron tree" when a crystal of the hexahydrate is added to a conc. soln. of **sodium silicate**; and R. C. Ray and P. B. Ganguly, the formation of silica gels by the action of ferric chloride on alkali silicate soln. M. Schneider found that when ferric chloride soln. are boiled in **glass** vessels, a product of the hydrolysis adheres to the walls of the vessel; no such adsorption occurs if the soln. is acidified. P. Rohland, and J. J. Shukoff and M. N. Sokolova noted the adsorption of ferric chloride from its aq. soln. by **clays**. L. Wunder observed that **ultramarine** is decomposed in the cold by a soln. of ferric chloride, and hydrogen sulphide is evolved. O. C. Magistad studied the exchange of bases in **zeolites**.

According to H. Plauson and G. Tischtschenko, anhydrous ferric chloride is reduced to ferrous chloride when it is fused with **sodium**. P. Nicolardot, and W. Biltz and W. Holverschheit found that sodium dissolves in a conc. hydrochloric acid soln. of ferric chloride, hydrogen is evolved, but little or no reduction of the ferric chloride occurs. P. Jannasch and T. W. Richards observed that very little reduction of the soln. occurs with sodium amalgam, and D. Tommasi found that some ferric hydroxide is precipitated by the action of the amalgam. J. N. von Fuchs, L. Storch, E. Beutel and A. Kutzlignig, A. Pickles, T. W. Hogg, F. Fischer, D. Miklosich, and W. C. Birch observed that ferric chloride is reduced to ferrous chloride by finely-divided **copper**. The dissolution of copper by soln. of ferric chloride was observed by W. Weissenberger, and M. Mayer. E. Bekier and S. Trzeciak observed that in the presence of an excess of ammonium chloride, the action of copper on a soln. of ferric chloride can be symbolized: $\text{Cu} + 2\text{FeCl}_3 \rightarrow \text{CuCl}_2 + 2\text{FeCl}_2$, followed by $\text{Cu} + \text{CuCl}_2 \rightarrow 2\text{CuCl}$. The velocity constant of the reaction $k = \{\log_e(a - \frac{1}{2}x_1) - \log_e(a - \frac{1}{2}x_2)\}v/S(t_2 - t_1)$, where a denotes the initial conc. of ferric and cupric chlorides; $\frac{1}{2}x_1$, and $\frac{1}{2}x_2$, the conc. of the ferric and cupric chlorides at the times t_1 and t_2 respectively; and S , the surface area of the plate. With the rate of stirring 1500 per min., k is 0.1508 at 15°, and 0.2044 at 25°, so that the temp. coeff. is 1.35 between 15° and 25°; the value of k is independent of the composition of the soln. starting with ferric chloride and ending with cupric chloride as the sole active constituents; and it increases with the rate of stirring. The value of k increases up to a limiting value as the conc. of the ammonium chloride increases, but beyond that stage it is independent of the conc. of the ammonium chloride. P. Schulz observed that in acetone soln., copper slowly reduces ferric chloride to ferrous chloride; and J. Schröder obtained a similar result in pyridine soln. G. Wetzlar found that powdered **silver** reduces an aq. soln. of ferric to ferrous chloride. The reaction was studied by N. A. Tananaeff, E. Beutel and A. Kutzlignig, and S. A. Voznesensky and V. Skvorzoff. P. Schulz observed no reduction in acetone soln., but J. Schröder observed that the reduction occurs in pyridine soln. C. St. Pierre, and J. Napier found that a dil., feebly acidic soln. of ferric chloride dissolves traces of **gold**, but J. Nicklès said that no dissolution occurs with cold or hot soln. P. Nicolardot, and D. J. Carnegie said that the soln. of ferric chloride is not reduced by gold, but G. Wetzlar said that some ferric chloride

is reduced by the gold. H. Schild said that $0.1N\text{-FeCl}_3$ at ordinary temp. slowly attacks gold forming aurous and ferrous chlorides. P. C. McIlhiney pointed out that a dil. soln. of ferric chloride in conc. hydrochloric acid does not attack gold if heated in a sealed tube provided air be excluded, but in the presence of air, the ferric chloride acts as a carrier of chlorine to the gold. H. N. Stokes used a 20 per cent. soln. of ferric chloride in half its vol. of 20 per cent. hydrochloric acid, free from nitric acid, and observed that at 200° there is a slow reaction $\text{Au} + 3\text{FeCl}_3 \rightleftharpoons \text{AuCl}_3 + 3\text{FeCl}_2$, which is reversed in the cold.

L. Hackspill found that at a dull red-heat, **calcium** reduces anhydrous ferric chloride: $2\text{FeCl}_3 + 3\text{Ca} = 3\text{CaCl}_2 + 2\text{Fe} + 317.4 \text{ Cals.}$ W. Biltz and W. Holverscheid observed no reduction of ferric chloride dissolved in conc. hydrochloric acid, although much hydrogen is developed. H. Plauson and G. Tischtschenko observed that when ferric chloride is melted with **magnesium** in an atmosphere of hydrogen, ferrous chloride is formed; and K. Seubert and A. Schmidt found that at a dull redness, the mixture becomes very hot, and the reaction proceeds violently forming magnesium and ferrous chlorides, and iron. J. Michajlenko and P. Muschinsky found that when a mixture of magnesium and hexahydrated ferric chloride is triturated at room temp., some hydrogen is evolved. S. Kern represented the reaction in aq. soln. by $2\text{FeCl}_3 + 3\text{Mg} + 6\text{H}_2\text{O} = 2\text{Fe}(\text{OH})_3 + 3\text{MgCl}_2 + 3\text{H}_2\text{O}$, when the soln. is free from dissolved air, and no reduction was observed by D. Tommasi. W. Biltz and W. Holverscheid observed no reduction in conc. hydrochloric acid soln. although hydrogen is copiously evolved; P. Jannasch and T. W. Richards observed a very incomplete reduction; and D. J. Carnegie, and H. N. Warren said that reduction is complete. K. Seubert and A. Schmidt observed that in warm, neutral soln., some ferrous hydroxide is precipitated; and D. Vitali obtained hydrogen, hydrated ferrous oxide, ferrous chloride, and iron as products of the reaction. K. Seubert and A. Schmidt, and A. Hönig also observed the precipitation of iron in acidic soln. P. Schulz found that magnesium slowly reduces ferric to ferrous chloride in acetone soln., and J. Schröder obtained similar results in pyridine soln. K. Schwenzer studied the reduction in ethereal soln. M. A. Parker and H. P. Armes observed that the reduction of ferric chloride in acidic soln. by magnesium is not influenced by a magnetic field. G. Wetzlar, and J. Napier found that **zinc** reduces ferric to ferrous chloride in aq. soln. D. J. Carnegie—*vide supra*, nascent hydrogen—supposed that the reduction by zinc dust is direct, and not *viâ* nascent hydrogen. If acid be not present, hydrated ferrous and ferric oxides are formed. According to E. Beutel and A. Kutzlknigg, a soln. of ferric chloride containing less than 100 grms. per litre has no effect on a bright surface of zinc, but more conc. soln. give a deposit containing iron. The rate of deposition increases with the conc. of the soln. until an optimum conc. of 500 grms. per litre is attained. A matt surface of zinc, obtained by a sand-blast, is slowly darkened by soln. with 50 grms. of FeCl_3 per litre. The spongy, non-adherent, grey layer has a metallic lustre, and contains irregular, microscopic granules of zinc and iron. The treatment of the deposit with distilled water gives no rust, but minute filaments of zinc hydroxide are formed. If sheet zinc be exposed for a long time to the action of soln. containing 500 to 1000 grms. of ferric chloride per litre, the primary deposit of iron is converted into compact, dark brown, hydrated ferric oxide. The hydrolysis of ferric chloride soln. furnishes hydrochloric acid which attacks the zinc, depositing a quantity of ferric hydroxide corresponding with the acid used in the production of zinc chloride. Some ferrous chloride is formed. The primary iron deposit formed in conc. ferric chloride soln. appears to undergo, more or less rapidly according to the degree of concentration, a change giving a brilliant, lustrous, but extremely brittle metallic layer, which breaks up spontaneously on reaching a certain thickness; this is found to be about 9×10^{-3} mm. The deposit contains zinc, and its composition varies with the concentration of the ferric chloride soln. Grey deposits are also obtained with alcoholic ferric chloride soln., and with dil. or conc. aq. ferrous sulphate. A coherent, tenacious, dove-grey deposit is similarly

produced in the presence of fluoride ions, whilst addition of a colloid (glue) yields a soln. which appears to contain iron as a dispersed phase, since after removal of a black deposit it possesses a dull grey colour. P. Schulz observed that zinc reduces ferric to ferrous chloride in acetone soln. The reduction of ferric to ferrous salts by zinc is utilized in analytical chemistry. D. L. Randall, L. Moyaux, and A. L. Beebe recommended amalgamated zinc, or amalgamated zinc in contact with platinum; G. T. Morgan, and J. H. Gladstone, a copper-zinc couple; and A. Gemmell, a zinc-magnesium or zinc-aluminium alloy. S. S. Bhatnagar and co-workers said that the reduction of ferric salts by zinc is reduced by a magnetic field; but M. Loeb, and F. A. Wolff obtained negative results in their examination of the influence of a magnetic field on the oxidation and reduction of iron salts. E. Beutel and A. Kutzligng studied the film of iron sometimes precipitated on zinc in soln. of over 100 grms. FeCl_3 per litre. J. Napier found that **cadmium** reduces an aq. soln. of ferric to ferrous chloride; and W. Heller studied the velocity of dissolution of cadmium in an aq. soln. of ferric chloride. P. Schulz observed that the reduction occurs slowly in acetone soln.; and J. Schröder, in pyridine soln. L. Wolf, D. Tommasi, D. J. Carnegie, and P. Nicolardot observed that a dil. acidified soln. of ferric chloride is reduced to ferrous chloride by **mercury**; and L. Meyer, and D. Borar said that in aq. soln. some mercurous chloride is formed. L. Q. McCay and W. T. Anderson, and P. Süss found that with vigorous shaking, the reduction $\text{FeCl}_3 + \text{Hg} = \text{FeCl}_2 + \text{HgCl}$ is complete in a few minutes. H. Schild added that at ordinary temp., 0.1N- FeCl_3 forms mercurous chloride, and at higher temp., mercuric chloride is formed. S. Popoff and co-workers found for the reaction $2\text{Fe}^{+++} + 2\text{Hg} \rightleftharpoons 2\text{Fe}^{++} + \text{Hg}_2^{++}$ the equilibrium constant 0.0180. Amalgamated zinc is also used for reducing ferric chloride.

E. Berger observed that a vigorous reduction occurs once the temp. of a mixture of powdered **aluminium** and anhydrous ferric chloride has been raised high enough to start the reaction. D. J. Carnegie, C. L. Schumann, F. J. R. Carulla, and W. H. Seamon reduced aq. soln. of ferric chloride to ferrous chloride. J. M. Weeren observed that the reaction proceeds more rapidly in vacuo than at ordinary press. H. Schild said that with neutral 0.1N- FeCl_3 , the soln. becomes dark red, and later a basic chloride is deposited, and ferrous chloride and hydrogen are produced. A. Hoenig added that the reduction is complete, and that, as in the case of magnesium and zinc, some iron is deposited. The solubility of aluminium in soln. of ferric chloride was studied by W. Heller. P. Schulz observed a slow reduction of ferric chloride in acetone soln.; and J. Schröder, in pyridine soln. F. Burkert, and H. H. Potter and W. Sucksmith used a soln. of ferric chloride for producing a film on aluminium, and also for etching the metal. M. A. Parker and H. P. Armes said that the reduction of ferric chloride in hydrochloric acid soln. by aluminium is influenced by a magnet; and S. S. Bhatnagar and co-workers said that, unlike the case with zinc, the reduction by aluminium is accelerated in a magnetic field. M. Loeb, and F. A. Wolff obtained negative results in similar cases of reduction.

G. Wetzlar, and J. Napier observed that a soln. of ferric chloride is reduced by **tin** to ferrous chloride at ordinary temp. H. Schild said that the conditions determine whether stannic or stannous chloride is formed. W. Heller studied the rate of dissolution of tin in an aq. soln. of ferric chloride. R. Kremann and F. Noss discussed the reaction $\text{Sn} + 2\text{FeCl}_3 = \text{SnCl}_2 + 2\text{FeCl}_2$. W. Biltz and W. Holverscheid found that with a 6 per cent. soln. of FeCl_3 , and 25 per cent. of HCl, no hydrogen is developed, and the reaction proceeds $\text{Sn} + 4\text{FeCl}_3 = \text{SnCl}_4 + 4\text{FeCl}_2$, with higher concentrations of acid, hydrogen is developed, and with higher concentrations of ferric chloride, the speed of the reaction is reduced. P. Schulz observed that tin slowly reduces a soln. of ferric chloride in acetone; and J. Schröder, a soln. in pyridine. I. A. Lösner said that a sat. aq. soln. of ferric chloride dissolves tin, and W. Heller said that the rate of soln. is proportional to the temp., and to the rate of stirring, but the temp. coeff. of the reaction is independent of the rate of stirring. The de-tinning of iron by soln. of ferric chloride was discussed by B. Schultze, and

R. Garcia. G. Wetzlar, J. Napier, H. Schild, and G. J. Hough found that **lead** reduces a soln. of ferric to ferrous chloride. J. Napier added that the action in a neutral soln. of ferric chloride is soon hindered by the formation of a protective crust of lead chloride; a boiling soln. acts more vigorously forming a deposit of hydrated ferric oxide. F. Stolba showed that the reduction of the ferric chloride proceeds rapidly with a hydrochloric acid soln. of ferric chloride containing some sodium chloride. P. Schulz said that lead does not act on an acetone soln. of ferric chloride.

E. F. Smith and H. C. Burr observed that **molybdenum** rapidly reduces a soln. of ferric to ferrous chloride, and molybdenum hexachloride is formed, $6\text{FeCl}_3 + \text{Mo} = 6\text{FeCl}_2 + \text{MoCl}_6$. C. H. Ehrenfeld said that the reaction in very dil., feebly acidified soln. of ferric chloride is complete. O. Jochem noticed that colloidal molybdenum reduces ferric chloride soln. C. H. Ehrenfeld found that **tungsten** attacks the soln. of ferric chloride with difficulty. H. Schild observed that **manganese** reduces 0.1N- FeCl_3 at ordinary temp. forming ferrous and manganous chlorides.

G. Wetzlar, and J. Napier observed that **iron** reduces an aq. soln. of ferric chloride; and J. Thomsen gave for the reaction $2\text{FeCl}_3 + \text{Fe} = 3\text{FeCl}_2 + 44.41$ Cals. Observations were also made by T. Andrews, and M. Berthelot; and M. Troilius found that with commercial iron, the iron oxide, sulphide, and phosphide, silica, and carbon remain as a residue, whilst the iron dissolves in the conc. soln. of ferric chloride. W. Spring thought that although ferric chloride soln. readily attack ordinary iron, it will probably not dissolve purified iron. The speed of the reaction increases with increasing dilution of the soln., and with less than 80 grms. of ferric chloride to 100 of water, there are two different reactions involved: (i) the direct dissolution of iron, and (ii) the action of hydrochloric acid, produced by hydrolysis, on the iron—the latter reaction is accompanied by the evolution of hydrogen. With 0.1N- FeCl_3 , H. Schild obtained a deposit of a basic chloride. The reaction was also studied by I. A. Lösner, W. Jufereff, D. J. Carnegie, W. H. Carothers and R. Adams, and R. G. van Name and D. U. Hill. D. A. McInnes and A. W. Contieri observed that by decreasing the external press., there is a slowing down of the reaction attended by the liberation of hydrogen, and an increase in the yield of ferrous chloride; in a feebly acidic soln., reducing the press. from 760 to 80 mm. increased the yield of ferrous chloride five times. A. F. Gehlen observed that iron reduces ferric to ferrous chloride in ethereal soln. M. A. Parker and H. P. Armes showed that the reduction of an hydrochloric acid soln. of ferric chloride, by metallic iron or aluminium, and the reduction of permanganate in acid soln. by metallic iron, are hastened in the magnetic field, there being a definite relationship between the extent of reduction and the strength of the field. The phenomena observed during the reduction of ferric chloride in hydrochloric acid soln. by magnesium are attributed to the formation of a magnetic deposit on the metal. The effect of stirring the soln. during reduction diminishes the difference in the extent of reduction in a given time in and out of the field. S. S. Bhatnagar and co-workers found that the reduction of ferric chloride soln. by iron, and aluminium is accelerated by a magnetic field. M. Loeb, and F. A. Wolff obtained negative results in examining the effect of a magnetic field on the reduction and oxidation of iron salts. J. Napier found that a neutral, aq. soln. of ferric chloride is quantitatively reduced by **cobalt** or **nickel** to ferrous chloride; and similar results were obtained by H. Schild, H. H. Potter and W. Sucksmith, H. N. Huntzicker and L. Kahlenberg, and H. S. Rawdon and M. G. Lorentz. P. Schulz found that cobalt and nickel do not act on ferric chloride in acetone soln.

C. St. Pierre, and R. Böttger found that a dil., feebly acid soln. of ferric chloride is reduced to ferrous chloride by boiling with **palladium** rather more quickly than is the case with platinum: $\text{Pd} + 2\text{FeCl}_3 = \text{PdCl}_2 + 2\text{FeCl}_2$. The transformation is quantitative; and A. C. Chapman observed that if the palladium be charged with hydrogen, the reduction occurs without the palladium dissolving—*vide supra*,

hydrogen. According to A. Béchamp and C. St. Pierre, C. St. Pierre, D. Tommasi, H. Schild, and P. Nicolardot, **platinum** is dissolved by a soln. of ferric chloride: $\text{Pt} + 2\text{FeCl}_3 = \text{PtCl}_4 + \text{FeCl}_2$. Freshly precipitated platinum, indeed, is completely dissolved in 10 mins. by the boiling soln., platinum sponge which has been heated to redness dissolves gradually in a hydrochloric acid soln. of ferric chloride. J. Napier, D. J. Carnegie, and C. Marie reported that ferric chloride is not reduced by platinum—*vide supra*, hydrogen. E. Baur noted that 5 to 10 c. mm. of gas, probably oxygen, is developed when platinum gauze is dipped in 10 c.c. of $M\text{-FeCl}_3$. B. H. Buxton and O. Teague, and H. D. Murray studied the coagulation of colloidal soln. of platinum by ferric chloride. C. R. A. Wright and C. Thompson found that a cell with platinum plates respectively in an alkaline soln. and in an acid soln. of ferric chloride furnishes a current, and oxygen is given off from the alkaline soln., and hydrogen from the acid soln.

For the action of **alkali hydroxides**, *vide supra*, the analytical reactions of iron. L. L. de Koninck found that **cuprous oxide** reacts with an acidified soln. of ferric chloride: $\text{Cu}_2\text{O} + 2\text{FeCl}_3 + 2\text{HCl} = 2\text{CuCl}_2 + 2\text{FeCl}_2 + \text{H}_2\text{O}$; and R. K. Meade obtained an analogous result with **cuprous hydroxide**. O. Ruff and B. Hirsch, K. List, and E. Kopp observed that **cupric oxide** rapidly decomposes a neutral, aq. soln. of ferric chloride forming a brown, cupriferous precipitate.

E. Kothny found that anhydrous ferric chloride reacts rapidly with cupric oxide, $3\text{CuO} + 2\text{FeCl}_3 = 3\text{CuCl}_2 + \text{Fe}_2\text{O}_3$; and at 600° , the reaction is completed in 15 mins. A. Béchamp observed that with **cupric hydroxide** dissolved in the soln. of ferric chloride, hydrated ferric oxide is precipitated, and subsequently dissolved. A soln. with a mol of ferric chloride takes up 1.25 mol of cupric oxide. The addition of cupric chloride to the sat. soln. precipitates the iron. N. Pappada also noted the peptization of cupric hydroxide by a soln. of ferric chloride. P. Nicolardot found that **silver oxide** precipitates hydrated ferric oxide from a dil. soln. of ferric chloride. A. Daubrée found that the vapour of ferric chloride passed over **calcium oxide** yields crystals of hæmatite; and J. M. van Bemmelen and E. A. Klobbie said that the product is calcium ferrite, not hæmatite. A. Béchamp observed that **zinc oxide** behaved very much like cupric hydroxide. J. Volhard noted that zinc oxide completely precipitates hydrated ferric oxide mixed with some zinc oxide from a soln. of ferric chloride at ordinary temp. P. Nicolardot found that a soln. of ferric chloride dissolved a little over 1 per cent. of zinc oxide, and the soln. gave a yellow precipitate when warmed. O. Ruff and B. Hirsch, and N. Pappada noted the peptization of **zinc hydroxide** by a soln. of ferric chloride; and similarly also with **cadmium hydroxide**. N. G. Chatterji and N. R. Dhar found that an alkaline soln. of **alkali zincate** precipitates from ferric chloride hydrated ferric oxide contaminated with zinc hydroxide. H. Rose observed that **mercuric oxide** in excess precipitates all the iron as hydrated ferric oxide from a soln. of ferric chloride, and mercuric oxychloride is formed at the same time; J. Volhard also found that the reaction is quantitative at ordinary temp., and utilized it in the separation of iron from manganese; and the process was studied by P. Nicolardot, C. Meineke, E. F. Smith and P. Heyl, B. Finzi, O. Ruff and B. Hirsch, and C. Zimmermann. A. Mailhe added that the precipitate is ferric oxychloride, not hydroxide. N. Pappada studied the peptization of **mercuric hydroxide** by soln. of ferric chloride.

A. Béchamp found that neutral, aq. soln. of ferric chloride slowly dissolve freshly precipitated **aluminium hydroxide**; hydrated ferric oxide is precipitated, and the soln. is gradually decolorized. The reaction was studied by E. A. Schenider, and N. Pappada. The so-called *ferric-alumina* used as a coagulant in water-softening is essentially a colloidal soln. of alumina peptized by ferric chloride. It was discussed by W. D. Hatfield, A. R. Moberg, A. R. Moberg and E. M. Partridge, L. B. Miller, E. J. Theriault and W. M. Clark. N. G. Chatterji and N. R. Dhar observed that an alkali soln. of **alkali aluminate** precipitates hydrated ferric oxide mixed with hydrated alumina from a soln. of ferric chloride.

P. Nicolardot observed that **lead oxide** precipitates hydrated ferric oxide. A. Béchamp said that **chromic hydroxide** does not dissolve in a neutral soln. of ferric chloride, although a dil. soln. may be coloured olive-green, or brownish-green; but N. Pappada found that chromic hydroxide is dissolved by conc. soln. of ferric chloride. A. Geuther observed that when a mixture of anhydrous ferric chloride and **chromium trioxide** is heated, chromyl chloride is formed: $2\text{FeCl}_3 + 3\text{CrO}_3 = \text{Fe}_2\text{O}_3 + 3\text{CrO}_2\text{Cl}_2$; and E. Comanducci observed that chromyl chloride is obtained by heating a mixture of **potassium dichromate**, ferric chloride, and conc. sulphuric acid. N. G. Chatterji and N. R. Dhar observed that with an alkaline soln. of **alkali chromite**, hydrated ferric oxide mixed with hydrated chromic oxide is precipitated. A. Geuther found that the reaction of **molybdenum trioxide** resembles that with chromium trioxide; and likewise also with **tungsten trioxide**. O. Ruff and B. Hirsch noted a reaction with **manganous hydroxide**; and W. Spring and G. de Boeck found that hydrated manganic oxide dissolves in aq. soln. of ferric chloride. The action of **ferric oxide and hydroxide** on soln. of ferric chloride is discussed in connection with the hydrosol, and hydrogel of ferric oxide. M. Kuhara found that when precipitated ferric hydroxide is boiled for a long time in 20 per cent. soln. of ferric chloride, hæmatite is formed. C. A. O. Rosell observed that ferric chloride is completely decomposed by **barium ferrate**, giving off chlorine, and oxygen, and forming ferric hydroxide and barium chloride. O. Ruff and B. Hirsch, and N. Pappada found that **cobalt hydroxide**, like ferric hydroxide, is peptized by a soln. of ferric chloride; and similarly with a soln. of **nickel hydroxide**. E. M. Walton observed that when the hexahydrate is triturated with **hexahydrated calcium chloride** liquefaction occurs. J. Schröder found that in pyridine soln. ferric chloride is completely reduced to ferrous chloride by **cuprous chloride**. R. Rosendahl studied the reaction. G. Herrmann, and S. G. Rawson found that cuprous chloride readily dissolves in a feebly acidified soln. of ferric chloride—*vide infra*; and C. Winther observed that the reduction $\text{CuCl} + \text{FeCl}_3 = \text{FeCl}_2 + \text{CuCl}_2$ is quantitative; he also found that **mercurous chloride** dissolves in a warm soln. of ferric chloride forming ferrous and mercuric chlorides. The reaction is complete but slow at room temp., and in ultra-violet light, the reaction is reversible. The reaction was found by J. Woost to be accelerated by hydrochloric acid. G. Carobbi found that **molybdenum trichloride** reduces ferric to ferrous salts; and W. Wardlaw and R. L. Wormell obtained a similar result with **molybdenum oxychloride**, MoOCl . E. Beckmann said that ferric chloride is insoluble in **chromyl chloride**; and F. E. Brown and J. E. Snyder, insoluble in **vanadium oxytrichloride**. Ferric chloride in aq. soln. is reduced by **stannous chloride**: $2\text{FeCl}_3 + \text{SnCl}_2 = 2\text{FeCl}_2 + \text{SnCl}_4$. L. Kahlenberg said that the reaction is bimolecular in acidic soln., and A. A. Noyes found it to be trimolecular. The reaction $\text{Sn}^{++} + 2\text{Fe}^{+++}$ was studied by F. G. Soper, W. C. Bray and M. H. Gorin, L. V. Pissarhevsky, and M. A. Rozenberg; and W. F. Timoféeff and co-workers investigated the accelerating action of neutral salts on the reduction of ferric chloride by stannous chloride. W. Schluttig titrated soln. of stannous chloride with ferric chloride, using indigo-carmin as internal indicator. E. M. Walton found that when the hydrate $\text{SnCl}_2 \cdot 2\text{H}_2\text{O}$ is triturated with the hexahydrate liquefaction occurs. The action of stannous chloride on ferric chloride in acetone soln. was found by P. Schulz to be similar to that in aq. soln.; likewise by A. Schier, in acetonitrile soln.; by E. Busch, in methylal soln.; and by J. Schröder, in pyridine soln., forming a complex salt. L. F. Nilson observed that **hydrochloroplatinous acid** reduces ferric to ferrous chloride; and **hydrochloroplatinic acid** forms a chloroplatinate. P. Schulz observed a dirty white precipitate of silver chloride is produced when **silver nitrate** is added to an acetone soln. of ferric chloride; and E. Busch, a white precipitate in soln. of ferric chloride in methylal. E. M. Walton found that when the hexahydrate, or the hemipentahydrate is triturated with **enneahydrated ferric nitrate**, liquefaction occurs.

Aq. soln. of ferric chloride dissolve sulphides of the heavy metals when assisted

by heat. The action of **alkali sulphides** has been discussed previously—*vide supra*, the analytical reactions of iron. E. Kothny found that the anhydrous chloride at 230° in an indifferent gas reacts completely with **cuprous sulphide** in accord with $4\text{FeCl}_3 + \text{Cu}_2\text{S} = 4\text{FeCl}_2 + 2\text{CuCl}_2 + \text{S}$. J. B. Cammerer found cuprous sulphide is attacked at ordinary temp. by an aq. soln. of ferric chloride, and a little gas is given off by warm soln.—either at 100° , or in a sealed tube at 120° —the reaction occurs in two stages: $\text{Cu}_2\text{S} + 2\text{FeCl}_3 = \text{CuCl}_2 + 2\text{FeCl}_2 + \text{CuS}$, and $\text{CuS} + 2\text{FeCl}_3 = \text{CuCl}_2 + 2\text{FeCl}_2 + \text{S}$. J. B. Cammerer said that no cuprous chloride is formed, but L. Gabba represented the reaction: $2\text{FeCl}_3 + \text{Cu}_2\text{S} = 2\text{FeCl}_2 + 2\text{CuCl} + \text{S}$. The reaction was studied by E. F. Anthon, E. Burschell, and J. Hanus. J. B. Cammerer represented the reaction of a 3 per cent. soln. of ferric chloride on **cupric sulphide** at ordinary temp., $\text{CuS} + 2\text{FeCl}_3 = \text{CuCl}_2 + 2\text{FeCl}_2 + \text{S}$; with a boiling soln., some hydrogen sulphide and sulphur dioxide are formed. Similar results were obtained in a sealed tube at 120° . The reaction was studied by E. F. Anthon, E. Burschell, and J. Hanus. The utilization of the reactions in the extraction of copper from unroasted sulphide ores was discussed by O. Chalandre, E. Cumenge and R. Wimmer, F. N. Flynn and R. H. Hatchett, E. Kopp, and G. P. Schweder; J. B. Cammerer represented the action of a 3 per cent. soln. of ferric chloride on **silver sulphide** by the equation: $\text{Ag}_2\text{S} + 2\text{FeCl}_3 = 2\text{AgCl} + 2\text{FeCl}_2 + \text{S}$. E. F. Anthon also studied the reaction of the soln. on silver sulphide, and on **cadmium sulphide**. F. Field found that neutral or acidic soln. of ferric chloride when boiled for a long time with **mercuric sulphide** form mercuric and ferrous chlorides, and sulphur, and, added J. B. Cammerer, with the intermediate formation of $2\text{HgS} \cdot \text{HgCl}_2$. J. B. Cammerer represented the action of a boiling, neutral soln. of ferric chloride on **stannous sulphide** by the equation: $\text{SnS} + 4\text{FeCl}_3 = \text{SnCl}_4 + 4\text{FeCl}_2 + \text{S}$; and on **stannic sulphide**: $\text{SnS}_2 + 4\text{FeCl}_3 = \text{SnCl}_4 + 4\text{FeCl}_2 + 2\text{S}$. Traces of sulphuric acid are also formed; and some stannic hydroxide appears as a result of the hydrolysis of the stannic chloride. E. F. Anthon observed that precipitated **lead sulphide** reacts with a boiling soln. of ferric chloride. The reaction was studied by J. B. Cammerer, D. J. Carnegie, A. Levallois, and T. Rieckher; and L. Gabba represented the reaction by the equation: $2\text{FeCl}_3 + \text{PbS} = 2\text{FeCl}_2 + \text{PbCl}_2 + \text{S}$. E. F. Anthon studied the action of a soln. of ferric chloride on **manganese sulphide**; and J. B. Cammerer represented the action of a 3 per cent. soln. by the equation: $\text{MnS} + 2\text{FeCl}_3 = \text{MnCl}_2 + 2\text{FeCl}_2 + \text{S}$; and with **ferrous sulphide**: $\text{FeS} + 2\text{FeCl}_3 = 3\text{FeCl}_2 + \text{S}$. If the ferrous sulphide has been obtained by a high temp. process, the rate of dissolution is slow; and M. Troilius added that when a cold, neutral, conc. soln. of ferric chloride is used as an etching liquid for iron or steel, the particles of included ferrous sulphide are not attacked. J. B. Cammerer represented the action of a boiling, 3 per cent. soln. of ferric chloride on **iron disulphide**, or **pyrite**, by the equation: $\text{FeS}_2 + 2\text{FeCl}_3 = 3\text{FeCl}_2 + 2\text{S}$; **chalcopyrite** is also partially decomposed. H. N. Stokes, and W. Wardlaw and F. H. Clews found that hot soln. of ferric chloride are reduced by pyrite or **marcasite**, and some sulphuric acid is formed. L. L. de Koninck represented the reaction with finely-powdered pyrite, in a sealed tube, at 170° to 200° , by the equation: $\text{FeS}_2 + 14\text{FeCl}_3 + 8\text{H}_2\text{O} = 15\text{FeCl}_2 + 2\text{H}_2\text{SO}_4 + 12\text{HCl}$. S. I. Levy and G. W. Gray represented the reaction with anhydrous ferric chloride and pyrite at 500° to 1000° by the equation: $8\text{FeCl}_3 + 4\text{FeS}_2 = 12\text{FeCl}_2 + 8\text{S}$ —*vide pyrite* and *pyrrhotite*. E. F. Anthon, and J. B. Cammerer studied the action of the soln. of ferric chloride on **cobalt sulphide**: $\text{CoS} + 2\text{FeCl}_3 = \text{CoCl}_2 + 2\text{FeCl}_2 + \text{S}$; and similar results were obtained with **nickel sulphide**.

F. L. Browne, and F. L. Browne and J. H. Mathews discussed the thermal value of the reaction between **sodium sulphate** and ferric chloride. P. Nicolardot observed that the addition of **alkali sulphate** to a dil. neutral, aq. soln. of ferric chloride results in the precipitation of a basic sulphate, but the reaction is complete only when the acidity of the soln. is very small. A boiling soln. of a gram of iron as FeCl_3 per litre is completely precipitated by a gram of **ammonium sulphate**.

J. W. Retgers found that a mixed soln. of ferric chloride and ammonium-sulphate deposits colourless ammonium sulphate on evaporation. G. Lunge studied the solubility of **calcium sulphate** in soln. of ferric chloride. According to Z. Karaoglanoff, **barium sulphate** exhibits a marked solubility in soln. of ferric chloride which depends on the conc. of the soln. of the ferric salt; but barium sulphate is insoluble in soln. of ferric chloride containing barium chloride. The adsorption of ferric chloride by the alkaline earth sulphates was studied by N. R. Dhar and co-workers, and L. de Brouckère; and J. W. Mellor discussed the bearing of this in analytical chemistry. L. de Brouckère also studied the absorption of ferric chloride by barium sulphate; G. Lunge, the solubility of **lead sulphate** in ferric chloride soln.; M. Berthelot, the thermal change which attends the admixture of a soln. of ferric chloride with **manganese sulphate** and **ferrous sulphate**; and F. G. Berend, the action of an ethereal soln. of ferric chloride on **manganic alum.** E. M. Walton found that if the hemipentahydrate is triturated with heptahydrated ferrous sulphate, liquefaction occurs.

The action of the **alkali carbonates** on soln. of ferric chloride has been discussed in connection with the analytical reactions of iron. K. Feist observed that if the hexahydrate be triturated with powdered crystals of sodium carbonate, some bubbling occurs, carbon dioxide is evolved, and a basic ferric carbonate is formed. H. Meyer represented the reaction with **copper carbonate** by the equation: $3\text{CuCO}_3 + 2\text{FeCl}_3 + 3\text{H}_2\text{O} = 3\text{CuCl}_2 + 2\text{Fe}(\text{OH})_3 + 3\text{CO}_2$, the copper and chlorine are retained very tenaciously by the precipitate. H. Rose observed that **silver carbonate** precipitates the iron quantitatively as ferric hydroxide mixed with silver chloride. H. Meyer found that **calcium carbonate** precipitates ferric hydroxide quantitatively in the cold; at high temp., in a sealed tube, H. de Sénarmont, E. Stirnemann, and M. Kuhara observed that crystals of ferric oxide (*q.v.*) are formed. C. Meineke studied the analogous precipitation of ferric hydroxide with **barium carbonate**. H. Meyer found that **magnesium, zinc, and lead carbonates** also decompose an aq. soln. of ferric chloride; and N. C. Christensen discussed the solubility of lead carbonate ores in a soln. of ferric chloride. M. Kuhara obtained magnetite and hæmatite by the prolonged boiling of **siderite** or **ferrous carbonate** in a 20 per cent. soln. of ferric chloride.

The complex salts of ferric chloride.—J. Nicklès, and P. T. Walden observed that the tendency of the ferric halides to form complex salts with other halides increases as the at. wt. of the halogen decreases. F. G. Donnan and H. Bassett studied the tendency of ferric chloride to form complex anions. H. Remy and H. J. Rothe studied homopolar combinations with the co-ordination numbers 5 and 7; and they added that the co-ordination number of an ion represents the number of electrons which must be added to the outer sphere to bring the total up to a value which represents a stable electronic configuration.

The seventeenth-century writings of Basilus Valentinus³ said that when a mixture of red vitriol and sal ammoniac is heated, a sublimate is obtained which deliquesces into an oily liquid. This product was probably a complex salt of ferric and ammonium chlorides. C. W. Scheele also obtained a complex salt of these two chlorides. P. L. Geiger, C. A. Winkler, and C. M. Marx made attempts to obtain a salt of uniform composition from mixed soln. of ammonium and ferric chlorides. They noted that the crystallizing power of the ammonium chloride

FIG. 587.—Equilibrium in the Mixed Solutions of Ammonium and Ferric Chlorides.

was favoured by the presence of ferric chloride so that instead of dendrites, cubic crystals were formed. The mixture obtained by evaporating a soln. of the two salts was for a time called *flores salis ammoniaci martiales*. O. Lehmann observed that the two salts on slow crystallization form a series of solid soln.; and this was

confirmed by J. W. Retgers. According to J. Fritzsche, the evaporation of a soln. of ammonium chloride with a large excess of ferric chloride, over sulphuric acid, furnishes red, rhombic crystals of **ammonium ferric pentachloride**, or *ammonium pentachloroferrate*, $(\text{NH}_4)_2\text{FeCl}_5 \cdot \text{H}_2\text{O}$, which might be mistaken for octahedra. The salt is not decomposed by water like the corresponding potassium salt. The crystals were prepared by P. T. Walden, and G. Neumann. C. Hensgen obtained it by the action of hydrogen chloride on a soln. of ammonium iron alum. F. A. Genth observed that on evaporating the mixed soln. at 15° to 20° , regular octahedra were formed, but at 25° to 40° , these crystals are transformed into hemiprismatic crystals, which, on exposure to air, return to their original form. F. W. J. Clendinnen could not confirm the existence of this salt, $2\text{NH}_4\text{Cl} \cdot \text{FeCl}_3 \cdot \text{H}_2\text{O}$. R. C. Wallace discussed the salts isomorphous with $(\text{NH}_4)_2\text{FeCl}_5 \cdot \text{H}_2\text{O}$; and G. Carobbi, the isomorphism of the salt with $(\text{NH}_4)_2\text{MoCl}_5 \cdot \text{H}_2\text{O}$. E. C. Feytis, T. Ishiware, and K. Honda and T. Ishiware gave for the magnetic susceptibility of $2\text{NH}_4\text{Cl} \cdot \text{FeCl}_3 \cdot \text{H}_2\text{O}$:

$\chi \times 10^6$	-179.8°	-108.4°	-21.9°	0°	53.6°	186.0°	392.9°
	132.7	79.5	54.3	49.9	43.2	32.6	22.8

J. L. C. Schroeder van der Kolk supposed that the solid soln. of the two salts are isomorphous mixtures of ammonium chloride with a regular modification of

FIG. 588.—Equilibrium in the Ternary System: $\text{NH}_4\text{Cl}-\text{FeCl}_3-\text{H}_2\text{O}$, at 25° .

FIG. 589.—Equilibrium in the Ternary System: $\text{NH}_4\text{Cl}-\text{FeCl}_3-\text{H}_2\text{O}$, at 60° .

ferric chloride, possibly $\text{FeCl}_3 \cdot 4\text{H}_2\text{O}$; but this hypothesis was contested by J. W. Retgers. A. Ritzel also regarded the product as a solid soln. of ammonium and ferric chlorides, and added that potassium sulphate or sodium nitrate in the soln. does not appear in the crystals. D. Balareff also discussed the subject. E. C. J. Mohr investigated the mutual solubilities at 15° , 25° , 35° , and 45° . Four phases were observed: (i) hydrated ferric chloride; (ii) J. Fritzsche's double salt; (iii) a series of solid soln.; and (iv) ammonium chloride. The ammonium chloride content at the triple point (1-2), and the ferric chloride at the triple point (2-3) are respectively almost unaffected by temp., so that the triple phase curves cut at about -15° , probably where the double salt phase must disappear. No definite conclusions were obtained with respect to the solid soln., but they are regarded as isomorphous mixtures of ammonium chloride and J. Fritzsche's double salt. The solid soln. were discussed by A. C. D. Rivett and F. W. J. Clendinnen, G. Bruni, A. Ritzel, and W. Eitel. Olive-brown needles of **ammonium ferric tetrachloride**, or *ammonium tetrachloroferrate*, $\text{NH}_4\text{Cl} \cdot \text{FeCl}_3$, were prepared but they soon changed into the ordinary double salt. F. W. J. Clendinnen obtained this salt as a stable phase at 60° , but not at 45° —*vide infra*; and K. Hachmeister found that it boils at 386° . E. C. J. Mohr also said that the regular crystals of J. L. C. Schroeder van der Kolk are probably produced when some ammonia is present. The crystallization of soln. of ferric chloride with increasing quantities of ammonium chloride furnished isotropic, regular crystals of **ammonium ferric heptachloride**, or

ammonium heptachlorodiferrate, $\text{NH}_4\text{Cl} \cdot 2\text{FeCl}_3 \cdot 4\text{H}_2\text{O}$. F. W. J. Clendinnen could not confirm the existence of this compound at 60° , and E. C. J. Mohr's own data at 45° do not agree with the existence of this compound as a stable solid phase. The solid soln. of the compound salts were studied by K. Spangenberg and A. Neuhaus, A. Neuhaus, and D. Balareff.

H. W. B. Roozeboom observed that at 15° , the solid phases in mixed soln. of the two salts are hexahydrated ferric chloride, J. Fritzsche's double salt, and solid soln. of ammonium chloride, with ferric chloride rising to 7 per cent. The results are illustrated by E. C. J. Mohr's curves for 15° , 25° , 35° , and 45° , Fig. 587, where the first curve for soln. in equilibrium with $\text{FeCl}_3 \cdot 6\text{H}_2\text{O}$, lies between the limits 9.30 to 9.93 mols FeCl_3 and 0 to 1.36 mols of NH_4Cl per 100 mols of water; the second curve for soln. in equilibrium with the complex salt $2\text{NH}_4\text{Cl} \cdot \text{FeCl}_3 \cdot \text{H}_2\text{O}$, has the limits 9.93 to 6.8 mols FeCl_3 and 1.36 to 7.8 mols NH_4Cl per 100 mols H_2O ;

TABLE XCIII.—THE TERNARY SYSTEM: $\text{NH}_4\text{Cl}-\text{FeCl}_3-\text{H}_2\text{O}$.

Sp. gr.	Percentage composition				Solid phases	
	Solution		Residue			
	NH ₄ Cl	FeCl ₃	NH ₄ Cl	FeCl ₃		
25°	1.132	24.14	7.64	87.22	2.57	Solid soln. AB
	1.327	16.05	28.97	84.36	7.36

	—	9.48	65.40	24.21	62.73	1.4.6 and 0.1.2
	1.620	8.57	65.70	14.49	69.10	
	1.745	1.57	75.37	9.99	75.14	
	—	1.15	76.31	3.55	77.54	
	—	0.25	78.10	—	—	
	—	0.18	78.20	1.12	79.20	
	1.798	—	78.42	—	—	

and the third curve for soln. in the presence of the solid soln. lies between the limits 6.8 to 0 mols FeCl_3 and 7.8 to 11.88 mols NH_4Cl per 100 mols of water. The soln. at the point of intersection of the two first curves is stable in presence of the hydrated ferric chloride and the double salt: that at the intersection of the second and third curves can exist in presence of the double salt and the mixed crystals containing the maximum amount of iron. The composition of the soln. at these points is independent of the quantity of the two solid phases. Whilst, however, the soln. at the first intersection is not further altered by any addition of ferric chloride, or by the addition of ammonium chloride up to the point where all the solid ferric chloride is converted into the double salt, the soln. at the second intersection is changed by the addition of one or other component, for each of these transforms one solid phase into the other. The curve for the double salt shows that this salt cannot be dissolved without undergoing decomposition. The mixed crystals contain the ferric chloride as Fe_2Cl_6 with 7 to 8 mols. H_2O ; but whether as an isotropic or ælotropic admixture remains undecided. The relation between

heptachloroferrate, $\{(C_3H_7)NH_3\}_4[FeCl_7]$, melting at 118° and softening at 110° ; and **butyl tetrachloroferrate**, $\{(C_4H_9)NH_3\}_3[FeCl_4]$, melting at 60.5° . F. Ephraim and S. Weiberg obtained black octahedra of **ammonium ferric antimony chloride**, $9NH_4Cl \cdot 2FeCl_3 \cdot 3SbCl_4$, from a soln. of the constituent chlorides in hydrochloric acid.

H. St. C. Deville observed that mixtures of sodium and ferric chlorides can be obtained melting to a mobile liquid at 200° . G. Neumann was unable to prepare

lithium ferric chloride; nor could **sodium ferric chloride** be prepared. F. W. Hinrichsen and E. Sachsels found that the solubility curve Fig. 592, at 21° , revealed the existence of a series of solid soln. of the component salts. Nor is there any evidence of the formation of a complex salt at temp. between 3° and 63° . G. Neumann came to a similar conclusion. The corresponding curves for potassium and ferric chlorides are shown in Fig. 592. They reveal the existence of a region, BC, where solid soln. are formed, and another region, AB, where the **potassium ferric pentachloroferrate**, or **potassium pentachloroferrate**, $K_2FeCl_5 \cdot H_2O$, is

FIG. 592.—Solubility Curves of Solution of Alkali and Ferric Chlorides.

the stable solid phase. C. Hensgen obtained this salt by passing hydrogen chloride into a conc. soln. of potassium iron alum. In agreement with J. Fritzsche, and G. Neumann, but not P. T. Walden, F. W. Hinrichsen and E. Sachsels found that this salt separates from a mixed soln. of the component salts when ferric chloride is in excess. The curve CB, Fig. 592, represents the effect of ferric chloride on the solubility of the alkali chloride. G. Malquori's study of the ternary system $KCl-FeCl_3-H_2O$, at 0° , showed that with soln. containing the following percentage proportions of the constituents

KCl	.	.	.	21.60	10.19	6.53	6.03	2.85	1.07	0
FeCl ₃	.	.	.	0	16.38	27.28	35.67	58.60	42.53	4.266
Solid phase				KCl		Solid solution		2KCl.FeCl ₃ .H ₂ O		FeCl ₃ .6H ₂ O

The zone of solid soln. does not appear at 25° when the compositions of the soln. are :

KCl	.	.	.	26.02	17.40	14.99	11.97	5.65	1.22	0
FeCl ₃	.	.	.	0	14.90	22.14	35.88	47.27	49.33	49.76
Solid phase				KCl		2KCl.FeCl ₃ .H ₂ O			FeCl ₃ .6H ₂ O	

At 35° , the solid phase for ferric chloride is the pentahydrate, and at 60° the dihydrate :

KCl	.	.	.	31.30	16.30	14.41	4.96	2.25	1.90	0
FeCl ₃	.	.	.	0	28.73	36.78	53.98	74.08	77.13	78.86
Solid phase				KCl		2KCl.FeCl ₃ .H ₂ O			FeCl ₃ .2H ₂ O	

G. Malquori studied the quaternary system: $\text{FeCl}_3\text{-KCl-HCl-H}_2\text{O}$ at 25° , and he found that:

PERCENTAGE COMPOSITION OF SOLUTION				SOLID PHASES
KCl	FeCl_3	HCl	H_2O	
11.97	35.88	—	52.15	KCl, and $\text{FeCl}_3 \cdot 2\text{KCl} \cdot \text{H}_2\text{O}$
1.50	1.15	39.20	58.15	ditto.
1.22	49.33	—	49.45	$\text{FeCl}_3 \cdot 2\text{KCl} \cdot \text{H}_2\text{O}$ and $\text{FeCl}_3 \cdot 6\text{H}_2\text{O}$
—	67.13	1.48	31.39	$\text{FeCl}_3 \cdot 6\text{H}_2\text{O}$ and $\text{FeCl}_3 \cdot 3\frac{1}{2}\text{H}_2\text{O}$
1.10	66.91	1.27	30.72	$\text{FeCl}_3 \cdot 6\text{H}_2\text{O}$, $\text{FeCl}_3 \cdot 3\frac{1}{2}\text{H}_2\text{O}$, and $\text{FeCl}_3 \cdot 2\text{KCl} \cdot \text{H}_2\text{O}$
—	69.93	3.96	26.11	$\text{FeCl}_3 \cdot 3\frac{1}{2}\text{H}_2\text{O}$, and $\text{FeCl}_3 \cdot 2\frac{1}{2}\text{H}_2\text{O}$
1.15	69.10	3.15	26.60	$\text{FeCl}_3 \cdot 3\frac{1}{2}\text{H}_2\text{O}$, $\text{FeCl}_3 \cdot 2\frac{1}{2}\text{H}_2\text{O}$, and $\text{FeCl}_3 \cdot 2\text{KCl} \cdot \text{H}_2\text{O}$
—	69.47	8.63	21.90	$\text{FeCl}_3 \cdot 2\frac{1}{2}\text{H}_2\text{O}$, and $\text{FeCl}_3 \cdot 2\text{H}_2\text{O}$
1.27	68.87	8.20	21.66	$\text{FeCl}_3 \cdot 2\frac{1}{2}\text{H}_2\text{O}$, $\text{FeCl}_3 \cdot 2\text{H}_2\text{O}$, and $\text{FeCl}_3 \cdot 2\text{KCl} \cdot \text{H}_2\text{O}$
—	70.30	12.30	17.40	$\text{FeCl}_3 \cdot 2\text{H}_2\text{O}$, and $\text{FeCl}_3 \cdot \text{HCl} \cdot 2\text{H}_2\text{O}$
1.71	70.10	11.85	16.34	$\text{FeCl}_3 \cdot 2\text{H}_2\text{O}$, $\text{FeCl}_3 \cdot \text{HCl} \cdot 2\text{H}_2\text{O}$ and $\text{FeCl}_3 \cdot 2\text{KCl} \cdot \text{H}_2\text{O}$

The results are plotted in Fig. 591. The point *h* represents a soln. sat. with HCl; *f*, one sat. with KCl and $\text{FeCl}_3 \cdot 2\text{KCl} \cdot \text{H}_2\text{O}$. The points *b'c'd'e'* refer to data of H. W. B. Roozeboom for the hydrates of ferric chloride. The region *fghi* represents a soln. sat. with KCl; *hfa'b'c'd'e'*, one sat. with $\text{FeCl}_3 \cdot 2\text{KCl} \cdot \text{H}_2\text{O}$; *aa'bb'*, one sat. with $\text{FeCl}_3 \cdot 6\text{H}_2\text{O}$; *bb'cc'*, one sat. with $\text{FeCl}_3 \cdot 3\frac{1}{2}\text{H}_2\text{O}$; *cc'dd'*, one sat. with $\text{FeCl}_3 \cdot 2\frac{1}{2}\text{H}_2\text{O}$; *dd'ee'*, one sat. with $\text{FeCl}_3 \cdot 2\text{H}_2\text{O}$; and *ee'l*, one sat. with $\text{FeCl}_3 \cdot \text{HCl} \cdot \text{H}_2\text{O}$. J. Fritzsche, and C. Hensgen prepared red crystals of this salt; and G. Neumann obtained it in reddish-brown octahedra and rhombic dodecahedra by adding potassium chloride to a hot, conc. soln. of ferric chloride in hydrochloric acid of sp. gr. 1.19. R. C. Wallace discussed the salts which are isomorphous with $\text{K}_2\text{FeCl}_5 \cdot \text{H}_2\text{O}$; and G. Carobbi, the isomorphism of $\text{R}_2\text{FeCl}_5 \cdot \text{H}_2\text{O}$ with $\text{R}_2\text{MoCl}_5 \cdot \text{H}_2\text{O}$, where $\text{R}=\text{NH}_4$ or K. According to F. W. Hinrichsen and E. Sachsel, the temp. of formation from its components is 22° to 22.5° ; and unlike J. Fritzsche, and P. T. Walden, they did not find the salt to be deliquescent, nor were they able to confirm A. Werner's product $3\text{KCl} \cdot \text{FeCl}_3$. O. Stelling and F. Olsson studied the X-ray spectrum of the pentachloride.

G. and P. Spacu observed the formation of the **potassium ferric ammino-chlorides**, $\text{K}_2[\text{FeCl}_5] \cdot 11\text{NH}_3$ with the vap. press. 145 mm. at -30° , and the heat of formation 8.83 Cals. per mol of NH_3 ; $\text{K}_2[\text{FeCl}_5] \cdot 6\text{NH}_3$ —with the vap. press. 37, 37, and 39 mm., respectively, at 0° , 14.9° , and 34.8° , and the heat of formation 11.75 Cals. per mol of NH_3 ; $\text{K}_2[\text{FeCl}_5] \cdot 6\text{NH}_3$ —with the vap. press. $p=47$ mm. at 78° , and the heat of formation 15.51 Cals. per mol of NH_3 ; and $\text{K}_2[\text{FeCl}_5] \cdot 2\text{NH}_3$ —with the vap. press. 7 and 2 mm. for the salt, respectively, with 2.15 and 2.06 mols NH_3 , at 120° .

P. T. Walden prepared **rubidium ferric pentachloride**, or *rubidium pentachloroferrate*, $\text{Rb}_2\text{FeCl}_5 \cdot \text{H}_2\text{O}$, by crystallization from a soln. containing 50 grms. of rubidium chloride and 10 grms. of ferric chloride. The rhombic crystals are easily soluble in water, and are identical with those to which R. Godefroy assigned the formula Rb_3FeCl_6 . The salt $\text{Rb}_2\text{FeCl}_5 \cdot \text{H}_2\text{O}$, was first prepared by G. Neumann in small yellow crystals by adding the alkali chloride to a hot, conc. soln. of ferric chloride in hydrochloric acid of sp. gr. 1.19. P. T. Walden prepared **cæsium ferric pentachloride**, or *cæsium pentachloroferrate*, $\text{Cs}_2\text{FeCl}_5 \cdot \text{H}_2\text{O}$, and also **cæsium ferric hexachloride**, or *cæsium hexachloroferrate*, by crystallization from aq. soln. of the component salts. F. W. Hinrichsen and E. Sachsel's observations on the range of stability of these two salts in aq. soln. are illustrated in Fig. 592. O. Stelling and F. Olsson studied the X-ray spectrum of the pentachloride. P. T. Walden described **cæsium ferric tetrachloride**, *cæsium tetrachloroferrate*, $\text{CsFeCl}_4 \cdot \frac{1}{2}\text{H}_2\text{O}$, but F. W. Hinrichsen and E. Sachsel were unable to confirm its existence. E. H. Duclaux reported **cæsium ferric octochloride**, $2\text{FeCl}_3 \cdot 2\text{CsCl} \cdot \text{H}_2\text{O}$; **cæsium ferric decachloride**, $2\text{FeCl}_3 \cdot 4\text{CsCl} \cdot 2\text{H}_2\text{O}$; and **cæsium ferric dodecachloride**, $2\text{FeCl}_3 \cdot 6\text{CsCl} \cdot 2\text{H}_2\text{O}$, but their existence has not been confirmed.

According to G. Herrmann, the crystallization of an aq. soln. of cuprous and

ferric chlorides furnishes green crystals of **cuprous ferric tetrachloride**, or *cuprous tetrachloroferrate*, $\text{CuFeCl}_4 \cdot 4\text{H}_2\text{O}$. Besides the *tetrahydrate*, the anhydrous salt can be obtained by fusion. The thermal diagram, Fig. 593, shows that the anhydrous salt melts at 320° , and there are two eutectics at 306° and 263° with respectively 50 and 88 per cent. of ferric chloride. H. Meyer observed that when basic copper chloride is dissolved in a soln. of ferric chloride, a precipitate of hydrated ferric oxide, contaminated with copper and chlorine, is formed. O. Lehmann studied solid soln. of ferric, cupric, and ammonium chlorides. G. Neumann could not prepare **silver ferric chloride**; G. Neumann could not prepare **calcium, strontium, or barium ferric chlorides**. I. Baschiloff and J. Wilniansky found that barium chloride can be salted out of its aq. soln. by ferric chloride. G. Malfitano and L. Michel discussed the effect of barium chloride on the hydrolysis of ferric chloride. J. W. Retgers studied the solid soln. of silver and ferric chlorides. He obtained **beryllium ferric pentachloride**, or *beryllium pentachloroferrate*, $\text{BeFeCl}_5 \cdot \text{H}_2\text{O}$, in small, orange-yellow crystals, by adding

FIG. 593.—Freezing-point Curves of the System : $\text{CuCl}-\text{FeCl}_3$.

FIG. 594.—Freezing-point Curves of the System : $\text{ZnCl}_2-\text{FeCl}_3$.

beryllium chloride to a hot, conc. soln. of ferric chloride in hydrochloric acid of sp. gr. 1.19, he also obtained large, brownish-yellow, hygroscopic crystals of **magnesium pentachloride**, or *magnesium pentachloroferrate*, $\text{MgFeCl}_5 \cdot \text{H}_2\text{O}$; but he could not prepare **zinc ferric chloride**, and **cadmium ferric chloride** by this process. G. Malfitano and L. Michel discussed the effect of magnesium chloride on the hydrolysis of ferric chloride; and I. I. Saslawsky studied the changes in vol. on mixing soln. of ferric and magnesium chlorides. G. Herrmann found that zinc and ferric chlorides have a eutectic at 214° with 70 per cent. of zinc chloride—Fig. 594—and that solid soln. are formed at both ends of the series. G. Malfitano and L. Michel discussed the effect of mercuric chloride on the hydrolysis of ferric chloride. G. Malquori studied the ternary system : $\text{AlCl}_3-\text{FeCl}_3-\text{H}_2\text{O}$ at 25° , but found neither compound—**aluminium ferric chloride**—nor solid soln.—Fig. 599. When associated with potassium chloride, G. Malquori observed :

PERCENTAGE COMPOSITION OF SOLUTION

KCl	AlCl_3	FeCl_3	H_2O
11.97	—	35.88	52.15
2.0	29.21	3.00	67.79
1.22	—	49.33	49.45
6.50	10.80	38.50	44.20
—	5.21	38.25	55.54
3.91	30.15	—	65.94

SOLID PHASES

KCl, and $\text{FeCl}_3 \cdot 2\text{KCl} \cdot \text{H}_2\text{O}$
KCl, $\text{FeCl}_3 \cdot 2\text{KCl} \cdot \text{H}_2\text{O}$, and $\text{AlCl}_3 \cdot 6\text{H}_2\text{O}$
$\text{FeCl}_3 \cdot 2\text{KCl} \cdot \text{H}_2\text{O}$, and $\text{FeCl}_3 \cdot 6\text{H}_2\text{O}$
$\text{FeCl}_3 \cdot 2\text{KCl} \cdot \text{H}_2\text{O}$, $\text{FeCl}_3 \cdot 6\text{H}_2\text{O}$, and $\text{AlCl}_3 \cdot 6\text{H}_2\text{O}$.
$\text{FeCl}_3 \cdot 6\text{H}_2\text{O}$, and $\text{AlCl}_3 \cdot \text{H}_2\text{O}$
KCl, and $\text{AlCl}_3 \cdot 6\text{H}_2\text{O}$

The results are plotted in Fig. 595. The point *e* represents soln. sat. with $\text{FeCl}_3 \cdot 6\text{H}_2\text{O}$, $\text{FeCl}_3 \cdot 2\text{KCl} \cdot \text{H}_2\text{O}$, and $\text{AlCl}_3 \cdot 6\text{H}_2\text{O}$; and *i*, soln. sat. with $\text{AlCl}_3 \cdot 6\text{H}_2\text{O}$, KCl, and $\text{FeCl}_3 \cdot 2\text{KCl} \cdot \text{H}_2\text{O}$. The region *fgie* represents soln. sat. with KCl; *bcei*, soln. sat. with $\text{FeCl}_3 \cdot 2\text{KCl} \cdot \text{H}_2\text{O}$; *abcd*, with $\text{FeCl}_3 \cdot 6\text{H}_2\text{O}$; and *edihg*, with $\text{AlCl}_3 \cdot 6\text{H}_2\text{O}$. In the case of the quinquinary system : $\text{FeCl}_3-\text{AlCl}_3-\text{KCl}-\text{HCl}-\text{H}_2\text{O}$ at 25° , it was observed that :

FeCl_3	AlCl_3	KCl	HCl	H_2O
—	0.09	1.18	33.21	65.52
3.0	29.21	2.0	—	65.79
0.98	0.25	1.87	38.25	58.65
1.15	—	1.50	39.20	58.15
38.50	10.80	6.50	—	44.20
69.91	1.31	1.01	11.0	16.77
69.81	1.02	—	11.75	17.42
70.01	—	1.71	11.85	16.34

SOLID PHASES

$\text{AlCl}_3 \cdot 6\text{H}_2\text{O}$, and KCl
 $\text{FeCl}_3 \cdot 2\text{KCl} \cdot \text{H}_2\text{O}$, KCl , and $\text{AlCl}_3 \cdot 6\text{H}_2\text{O}$
 $\text{FeCl}_3 \cdot 2\text{KCl} \cdot \text{H}_2\text{O}$, KCl , and $\text{AlCl}_3 \cdot 6\text{H}_2\text{O}$
 $\text{FeCl}_3 \cdot 2\text{KCl} \cdot \text{H}_2\text{O}$, and KCl
 $\text{FeCl}_3 \cdot 2\text{KCl} \cdot \text{H}_2\text{O}$, $\text{FeCl}_3 \cdot 6\text{H}_2\text{O}$, and $\text{AlCl}_3 \cdot 6\text{H}_2\text{O}$
 $\text{FeCl}_3 \cdot 2\text{KCl} \cdot \text{H}_2\text{O}$, $\text{FeCl}_3 \cdot \text{HCl} \cdot 2\text{H}_2\text{O}$, $\text{AlCl}_3 \cdot 6\text{H}_2\text{O}$,
 and $\text{FeCl}_3 \cdot 2\text{H}_2\text{O}$
 $\text{FeCl}_3 \cdot \text{HCl} \cdot 2\text{H}_2\text{O}$, $\text{FeCl}_3 \cdot 2\text{H}_2\text{O}$, and $\text{AlCl}_3 \cdot 6\text{H}_2\text{O}$.
 $\text{FeCl}_3 \cdot \text{HCl} \cdot 2\text{H}_2\text{O}$, $\text{FeCl}_3 \cdot 2\text{KCl} \cdot \text{H}_2\text{O}$, and $\text{FeCl}_3 \cdot 2\text{H}_2\text{O}$

The results are plotted in Fig. 596. The area *aelm* represents soln. sat. with $\text{AlCl}_3 \cdot 6\text{H}_2\text{O}$ and KCl ; *ebmn*, with KCl and $\text{FeCl}_3 \cdot 2\text{KCl} \cdot \text{H}_2\text{O}$; *mefg*, with $\text{FeCl}_3 \cdot 2\text{KCl} \cdot \text{H}_2\text{O}$ and $\text{AlCl}_3 \cdot 6\text{H}_2\text{O}$; *fdgh*, with $\text{AlCl}_3 \cdot 6\text{H}_2\text{O}$, and solids of the system $\text{FeCl}_3\text{--HCl--H}_2\text{O}$; and *icfg*, with $\text{FeCl}_3 \cdot 2\text{KCl} \cdot \text{H}_2\text{O}$, and solids of the system $\text{FeCl}_3\text{--HCl--H}_2\text{O}$. G. Neumann, and F. Wöhler and A. Ahrens reported red, prismatic crystals of thalious ferric chloride to be formed from aq. soln. of the component salts, but they are decomposed by water. According to G. Scarpa, when a mixture

FIG. 595.—The Quaternary System : $\text{FeCl}_3\text{--AlCl}_3\text{--KCl--H}_2\text{O}$ at 25° .

FIG. 596.—The Quinquenary System : $\text{FeCl}_3\text{--AlCl}_3\text{--KCl--HCl--H}_2\text{O}$ at 25° .

of the thalious and ferric chlorides is fused, some of the latter is volatilized, and the thermal diagram could not be completed when more than 62 molar per cent. is present. The diagram, Fig. 597, shows that there is a eutectic at 266° with 26 molar per cent. of ferric chloride and a maximum at 290° corresponding with **thalious ferric pentachloride**, or *thalious pentachloroferrate*, Ti_2FeCl_5 , which is stable on fusion. There is another eutectic at 220° . With high proportions of ferric chloride, crystallization sets in only at a relatively high temp., so that with

FIG. 597.—Freezing-point Curves of the System : $\text{TiCl}_3\text{--FeCl}_3$.

FIG. 598.—Freezing-point Curves of the System : $\text{FeCl}_3\text{--PbCl}_2$.

62 per cent. ferric chloride, crystallization begins at 299° which is near the m.p. of ferric chloride. It is hence inferred that there is a second maximum beyond this temp. G. Neumann was unable to prepare **lead ferric chloride**, and **manganous ferric chloride** in acidic soln. G. Herrmann observed that lead and ferric chlorides have a eutectic at 178° with 50 per cent. of ferric chloride—Fig. 598. K. Johansson observed a mineral of the composition $\text{Pb}(\text{Cl},\text{OH})_2 \cdot 4\text{PbO} \cdot 2\text{Fe}_2\text{O}_3$, at Jacobsberg, Sweden. It was called **hæmatophanite**, in allusion to its dark reddish-brown colour

—thin plates are blood-red. The crystals are tetragonal with the axial ratio $a:c=1:1.95$. The sp. gr. is 7.70; the hardness 2 to 3; and the optical character is negative. The cleavage is micaceous. For the complex with antimony pentachloride, *vide supra*.

According to J. Lefort,⁴ **ferrosic chloride**, $\text{Fe}_3\text{Cl}_8.18\text{H}_2\text{O}$, or $\text{FeCl}_2.2\text{FeCl}_3.18\text{H}_2\text{O}$ —according to H. Chandra, the formula should be $\text{Fe}_3\text{Cl}_8.10\text{H}_2\text{O}$ —is formed when

FIG. 599.—Equilibrium in the Ternary System: $\text{AlCl}_3\text{--FeCl}_3\text{--H}_2\text{O}$ at 25° .

ferric oxide is dissolved in conc. hydrochloric acid, and the soln. evaporated over conc. sulphuric acid. The yellow, crystalline mass is very deliquescent, it melts at 48° ; loses water at 50° , and hydrogen chloride at 90° . G. Neumann doubted the existence of this salt, but H. Chandra confirmed J. Lefort's deductions. J. W. Retgers observed no evidence of the formation of solid soln. when a mixed soln. of ferrous and ferric chlorides is crystallized; and H. Remy and H. J. Rothe observed no sign of the formation of a double salt. According to A. Werner's co-ordination scheme, the salt is formulated $\text{Fe}''[\text{Fe}'''\text{Cl}_4]_2$, and the decahydrate, $[\text{Fe}''(\text{H}_2\text{O})_6][\text{Fe}'''\text{Cl}_4].4\text{H}_2\text{O}$.

C. Hensgen reported an intermediate chloride, $\text{Fe}_3\text{Cl}_4.5\text{H}_2\text{O}$, to be formed in green needles by dissolving ferrous sulphate in conc. hydrochloric acid, and treating the soln. with hydrogen chloride and air. H. Chandra also obtained a product $\text{Fe}_3\text{Cl}_7.10\text{H}_2\text{O}$, by evaporating in the absence of air a hydrochloric acid soln. of the basic carbonate $\text{NH}_4[\text{Fe}_2'''\text{Fe}''.(\text{CO}_3)_3\text{O}]2\text{H}_2\text{O}$. He said that the salt is the chloride of a base $\text{Fe}_2'''\text{Fe}''(\text{OH})_7.n\text{H}_2\text{O}$.

§ 38. The Iron Bromides

Iron forms **ferrous bromide**, FeBr_2 , and **ferric bromide**, FeBr_3 , and their hydrates; and there is also a **ferrosic bromide**, Fe_3Br_8 , and its hydrates; as well as a mixed chlorobromide. According to P. Höfer,¹ the commercial iron bromide approximates in composition to ferrosic bromide, $\text{Fe}_3\text{Br}_8 \cdot n\text{H}_2\text{O}$, but with rather less than this proportion of bromine. Its preparation and properties were described by K. Kubierschky, F. Chemnitius, and W. Hüttner.

The preparation of ferrous bromide.—According to J. B. Berthémot, bromine does not act on iron in the cold, but, as shown by C. Löwig, J. von Liebig, and J. B. Berthémot, if iron be heated to dull redness in bromine, **ferrous bromide**, FeBr_2 , is formed, and it solidifies to a yellow, crystalline mass. A. Scheufelen said that the anhydrous bromide is most readily prepared by passing a current of carbon dioxide and bromine vapour through a hot porcelain tube containing metallic iron. Ferrous bromide sublimes forming greenish-yellow scales, which deliquesce on exposure to air. A. E. Nordenskjöld obtained ferrous bromide by passing hydrogen bromide over heated iron; and G. P. Baxter and co-workers heated iron in a current of dry nitrogen and hydrogen bromide at a temp. high enough to sublime the product. The product was contaminated by some phosphate—derived possibly from an impurity in the hydrogen bromide. The sublimate was heated in a current of dry nitrogen and hydrogen bromide until it showed no trace of ferric bromide when tested with ammonium thiocyanate. The anhydrous salt can also be obtained by heating one of the hydrates in a current of nitrogen and hydrogen bromide at about 400° . F. Chemnitius, and A. Ferrari and F. Giorgi used this process; and W. Biltz and G. F. Hüttig added that the temp. of dehydration must be kept low. W. Biltz and E. Birk recommended purifying the salt by resublimation in a current of hydrogen bromide. C. Löwig said that ferrous bromide is formed when iron filings are heated with ammonium bromide, when ammonia and hydrogen are evolved. L. Hackspill and R. Grandadam obtained ferrous bromide by heating an alkali bromide with iron at a high temp.: $\text{Fe} + 2\text{NaBr} = 2\text{Na} + \text{FeBr}_2$. P. Höfer obtained ferrous bromide by heating hydrated ferrosic bromide to 400° or 500° in the absence of air; and W. Hieber and G. Bader obtained it by the photochemical

decomposition of ferrous tetracarbonyl bromide. F. W. Bergstrom obtained the salt by the action of a soln. of ammonium bromide in liquid ammonia on iron wire.

The hydrates of ferrous bromide.—According to C. Löwig, an aq. soln. of ferrous bromide is formed when the anhydrous salt is dissolved in water; and when iron is dissolved in bromine water, or in hydrobromic acid. Similar processes were employed by J. B. Berthemot, C. Chojnacky, H. Lescœur, J. H. Long, F. A. Volkmann, and C. R. A. Wright and C. Thompson. When the aq. soln. is evaporated, it deposits crystals of the *hexahydrate*, $\text{FeBr}_2 \cdot 6\text{H}_2\text{O}$. A. Étard found the percentage solubility, S , of ferrous bromide in water to be:

	-20°	0°	10°	20°	30°	40°	60°	80°	100°
S	47.0	50.3	52.4	53.5	55.0	56.2	59.0	61.5	64.0

According to F. A. Volkmann, the solid phase between 10° and 47° is the hexahydrate, and above 47°, the *tetrahydrate*, $\text{FeBr}_2 \cdot 4\text{H}_2\text{O}$, so that the transition point is 47°. If the conc. soln. approximating $\text{FeBr} + 9.5\text{H}_2\text{O}$, be cooled to -10° to 30°, small, green, silky crystals of the hexahydrate are formed. F. Schimmel studied the solubility curves of ferrous bromide, and found for the solubility S grms. of FeBr_2 in 100 grms. of soln.

	-6.1°	-25.0°	-43.6°	-37.0°	-29.3°	30°	49.0°	57°	83.0°	132.0°
S	18.5	35.2	42.25	43.5	47.65	55.4	58.45	58.8	63.3	70.2
	Ice			$\text{FeBr}_2 \cdot 9\text{H}_2\text{O}$		$\text{FeBr}_2 \cdot 6\text{H}_2\text{O}$	$\text{FeBr}_2 \cdot 4\text{H}_2\text{O}$		$\text{FeBr}_2 \cdot 2\text{H}_2\text{O}$	

The results are plotted in Fig. 600. The eutectic temp. is -43.6° with 42.25 per cent. of ferrous bromide. There is a transition temp. at -29.3° corresponding

FIG. 600.—The Solubility of Ferrous Bromide in Water.

with the passage of the enneahydrate, $\text{FeBr}_2 \cdot 9\text{H}_2\text{O}$, to the hexahydrate. The hexahydrate was studied by J. B. Berthemot, J. Eggert and J. Reitstötter, H. Lescœur, C. Löwig, and F. A. Volkmann. F. Schimmel found that at 49°, the hexahydrate passes to the tetrahydrate studied by G. P. Baxter and co-workers, and F. A. Volkmann. F. Schimmel found that the tetrahydrate passes to the *dihydrate*, $\text{FeBr}_2 \cdot 2\text{H}_2\text{O}$, at 83°. H. Lescœur's measurements of the vap. press. also agreed with the existence of the dihydrate, as well as of a *monohydrate*, $\text{FeBr}_2 \cdot \text{H}_2\text{O}$.

The physical properties of ferrous bromide.—J. von Liebig, C. Löwig, and A. Scheufelen said that the **colour** of the salt crystallized from the molten state is greenish-yellow; W. Biltz and G. F. Hüttig said the salt obtained from the dehydration of the hydrate is ochre-yellow; G. P. Baxter and co-workers said the colour of the salt is light yellow or dark brown. F. Schimmel said that all the hydrates of ferrous bromide are green, and that the "red, hygroscopic powder" of commerce owes its colour to contamination with ferric bromide. W. Biltz and E. Birk said that the sublimed salt forms yellow, transparent scales; A. E. Nordenskjöld found that the sublimed **crystals** are white, six-sided, hexagonal, and uniaxial. A. Ferrari and F. Giorgi observed that the **X-radiogram** corresponds with a hexagonal space-lattice of the cadmium iodide type, being composed of three orthogonal prisms with rhombic bases, each containing a mol. of FeBr_2 . The parameters $a=3.740 \text{ \AA}$, and $c=6.171 \text{ \AA}$, or $a:c=1:1.65$. W. Hieber and E. Levy studied the lattice energy. G. P. Baxter found the **specific gravity** to be 4.636 at 25°/4°; W. Biltz and E. Birk gave 4.624 at 25°/4°; and A. Ferrari and F. Giorgi calculated 4.790 from the vol. of the elementary cell. W. Biltz gave 46.65 for the mol. vol. at 25°; F. Ephraim and co-workers, W. Biltz, and I. I. Saslawsky studied the change in vol. which attends the formation of the

compound from its elements. A. Heydweiller found that soln. with C mol of FeBr_2 per litre have a sp. gr. at $18^\circ/4^\circ$, reduced to a vacuum:

C	0.25	0.50	1.0	1.5	2.0	2.5
Sp. gr.	1.04692	1.0932	1.1850	1.2756	1.3660	1.4560

F. Schimmel found that the **boiling-point** of a sat. soln., with 70.2 per cent. of FeBr_2 , is 132° ; and H. Lescœur gave for the **vapour pressure**, p mm., of the sat. soln.:

	40°	50°	60°	70°	80°	90°
p	24	33	53	85	118	180

For the vap. press. of the dihydrate at 110° , 120° , and 210° , he gave 90, 120, and 210 mm. respectively; and for the monohydrate at 160° , $p=195$ mm. C. Löwig, and A. Scheufelen observed that the salt melts and volatilizes at a high temp. A. Ferrari and F. Giorgi gave 684° for the **melting-point** of the anhydrous salt. A. Ferrari discussed the relation between the m.p. and the space-lattice. The **transition-points** of the different hydrates are indicated above; and J. Eggert and J. Reitstötter discussed the transition: $\text{FeBr}_2 \cdot 6\text{H}_2\text{O} \rightleftharpoons \text{FeBr}_2 \cdot 4\text{H}_2\text{O} + 2\text{H}_2\text{O}$ in soln. M. Berthelot gave for the **heat of formation** ($\text{Fe}, \text{Br}_{2\text{gas}}, \text{Aq.}$) = 85.9 Cals., and ($\text{Fe}, \text{Br}_{2\text{liq.}}, \text{Aq.}$) = 78.5 Cals.; J. Thomsen, 78.07 at 18° ; W. Hieber and A. Woerner, 59.87 Cals.; and T. Andrews, 80.8 Cals. J. Thomsen gave ($\text{Fe}, 2\text{HBr}, \text{Aq.}$) = 24.81 Cals. Observations were also made by P. A. Favre and J. T. Silbermann. F. Ephraim and O. Schütz discussed some relationships of the heat of formation. J. Thomsen measured the heat of soln. of iron in hydrobromic acid; and M. Berthelot, the heat of neutralization. G. Beck studied the **free energy** and the **entropy** of the salt. W. Hieber and E. Levy studied the **lattice energy** of the crystals.

G. Limann measured the **index of refraction** of aq. soln. of C eq. of ferrous bromide per litre, and obtained:

C	0	0.5	1.0	2.0	4.0	5.0
μ $\left\{ \begin{array}{l} H\alpha \\ D \\ H\beta \\ H\gamma \end{array} \right.$	1.33139 1.33322 1.33737 1.34060	1.34042 1.34237 1.34681 1.35032	1.34931 1.35137 1.35609 1.35982	1.36679 1.36910 1.37439 —	1.40043 1.40314 1.41035 —	1.41686 1.41982 1.42671 —

Observations were also made by A. Heydweiller, who also gave for the **molecular refraction** of conc. up to 5*N*- FeBr_2 , 26.10; and G. Limann, 26.06 on the μ^2 -formula at 18° with Na-light. There is a small increase in the **dispersion** with decreasing concentration. A. Heydweiller gave for the eq. **electrical conductivity** of soln., λ mho, with an eq. of FeBr_2 per litre, at 18° :

C	0.5	1.0	2.0	3.0	4.0	5.0
λ	72.3	64.3	50.0	41.94	33.65	26.25

with the limiting value $\lambda_\infty=113$ at 18° . G. Limann discussed the relations between the electrical conductivity and the refraction of the soln. W. Isbekoff measured the decomposition potential of soln. of ferrous bromide in fused zinc bromide. L. Pauling and M. L. Huggins studied the magnetic properties.

The chemical properties of ferrous bromide.—G. P. Baxter observed that when anhydrous ferrous bromide is heated in moist **hydrogen**, it is slowly reduced; the reduction is complete at a high temp. The anhydrous salt is stable in dry **air**; but in ordinary air, A. Scheufelen observed that the salt gradually acquires a brown crust; and is deliquescent. C. Löwig observed that when heated in air, some of the salt volatilizes, and some ferric oxide is formed, but P. Höfer was unable to detect the formation of ferric bromide. C. Löwig, and G. P. Baxter and co-workers observed that the aq. soln. is oxidized by air, becoming darker in colour, and depositing a basic salt; H. Lescœur added that the bromide soln. oxidizes more rapidly than the chloride soln. C. Löwig observed that **water** vapour at a red-heat converts ferrous bromide into hydrogen bromide and ferric oxide.

The solubility in water is discussed above. J. H. Long found that the degree of **hydrolysis** of 0.54*N*-FeBr₂, calculated from the rate of inversion of cane-sugar, is 0.109 per cent. G. J. Fowler observed that ferrous bromide is decomposed when heated in **ammonia**, as in the case with ferrous chloride. Ammonia is absorbed by ferrous bromide forming hexa-, di-, and monoammines. The ranges of existence observed by W. Biltz and co-workers are summarized in Fig. 601. W. Biltz and

FIG. 601.—Dissociation Pressures of the Ammines of Ferrous Bromide.

W. Hieber and G. Bader obtained it by passing tetracarbonyl dibromide over iron; and E. Weitz and H. Müller, by the action of ammonium bromide on an ammoniacal soln. of ferrous hexamminoacetate, or by passing ammonia into a soln. of 5 grms. of hexahydrated ferrous bromide and 10 grms. of ammonium bromide in 25 c.c. of water. The salt prepared dry is a voluminous white powder, and when prepared by the wet process it forms pale-green octahedra which, according to W. Biltz, belong to the cubic system; and the space-lattice has the parameter $a=10.51$ Å., with the atoms Br, and Fe, and the molecule NH₃ arranged as in the hexamminochloride. G. B. Naess and O. Hassel studied the sphere of action of the anion. W. Biltz and E. Birk found the sp. gr. to be 1.812 at 25°/4°, so that it occupies about 2.76 times the vol. of the salt free from ammonia. The dissociation press., p mm., was measured by F. Ephraim, and W. Biltz and co-workers, and the results are summarized in Fig. 601.

	63°	84.5°	105.5°	115.3°	130°	149°	153°
p	22	48	114	175	329	683	775

F. Müller gave 44° to 149° for the dissociation temp. G. Beck gave 478 cal. for the heat of formation. W. Biltz, and W. Biltz and G. F. Hüttig gave for the heat of formation, FeBr₂+6NH_{3gas}=94.02 Cals., or 15.67 Cals.—F. Ephraim gave 14.9 Cals.—per mol of ammonia; and FeBr₂.2NH₃+4NH_{3gas}=53.35 Cals., or 13.34 Cals. per mol of ammonia. The free energy of the reaction FeBr₂+6NH_{3gas}=FeBr₂.6NH₃, at 27°, is 37.14 Cals., or 6.19 Cals. per mol of ammonia. W. Biltz and co-workers showed that salt is a hexamine-cation, [Fe(NH₃)₆]Br₂. F. Ephraim added that the salt is oxidized by air more slowly than the hexamminochloride. F. W. Bergstrom also made some observations. According to F. Ephraim, and W. Biltz and G. F. Hüttig, when the hexamine is heated, it forms **ferrous diamminobromide**, FeBr₂.2NH₃, which, at 215°, 230°, and 277°, has the respective dissociation press. 11.5, 23.5, and 126 mm., and the respective heats of dissociation, 21.9, 21.9, and 22.3 Cals.; and F. Müller gave over 300° for the dissociation temp. W. Biltz found that the heat of formation FeBr₂+2NH_{3gas}=40.65 Cals., or 20.32 Cals. per mol of ammonia; and FeBr₂.NH₃+NH₃=19.87 Cals. The free energy of the reaction FeBr₂+2NH_{3gas}=FeBr₂.2NH₃, at 27°, is 21.18 Cals. or 10.59 Cals. per mol of ammonia. W. Biltz observed that the anion is co-ordinated in the complex, and unlike the hexamine, the diammine is a molecular compound. W. Hieber and E. Levy studied the energy of formation. F. Ephraim, and W. Biltz and G. F. Hüttig showed that the diammine forms **ferrous aminobromide**, FeBr₂.NH₃, as a dark grey mass, which, at 215°, 230°, and 277°, has the respective dissociation press. 5.7, 9.7, and 61.5 mm., and the respective heats of dissociation

22.6; 22.8, and 23.1 Cals. W. Biltz observed that the heat of formation $\text{FeBr}_2 + \text{NH}_{3\text{gas}} = 20.78$ Cals.; and the free energy of formation, at 27° , is 11.08 Cals. The complex resembles that of the diammine, and is not like the hexammine. F. Ephraim and co-workers studied the mol. vol. of the amines. F. W. Bergstrom observed that an ammonia soln. of **potassium amide** produces no definite products with ferrous bromide. V. Thomas, and W. Manchot found that both aq. and alcoholic soln. of ferrous bromide absorb **nitric oxide** until the solute corresponds with **ferrous nitrosyl bromide**, $\text{FeBr}_2 \cdot \text{NO}$, although that salt has not been isolated. V. Thomas also found that the dry, anhydrous salt absorbs **nitrogen peroxide** to form **ferrous tetrinitroxylbromide**, $4\text{FeBr}_2 \cdot \text{NO}_2$, which retains the absorbed gas even in vacuo. If moisture be present, more gas is absorbed, but a reaction sets in which is attended by the evolution of bromine. H. Grossmann and F. Hünseler observed that **phenylhydrazine** forms the complex $\text{FeBr}_2 \cdot 6(\text{C}_6\text{H}_5)\text{NH}(\text{NH}_2)$.

W. Hieber and co-workers, H. Hock and H. Stuhlmann, and W. Mittasch observed that **iron carbonyl**, $\text{Fe}(\text{CO})_5$, in pentane or other solvent reacts with bromine forming **ferrous tetracarbonyl bromide**, $\text{Fe}(\text{CO})_4\text{Br}_2$. The mol. wt. in ethylene bromide is 330.7; in nitrobenzene, 339.7; and in acetic acid, 323.3—the theoretical value is 327.68. The heat of formation is $(\text{FeBr}_2, 4\text{CO}) = 26$ Cals. The bromide decomposes in sunlight; and at press. below 750 mm., or at temp. above 55° , into ferrous bromide and carbon monoxide. It is fairly stable in dry air but is decomposed by water into carbon monoxide and ferrous bromide; with ammonia it forms ferrous hexamminobromide; and with pyridine, $\text{FeBr}_2 \cdot 2\text{C}_5\text{H}_5\text{N}$, and $\text{FeBr}_2 \cdot 4\text{C}_5\text{H}_5\text{N}$. It is decomposed by ethyl acetate or acetic anhydride. If bromine acts on the iron pentacarbonyl at a low temp., **ferrous pentacarbonyl bromide**, $\text{Fe}(\text{CO})_5\text{Br}_2$, is formed; the complex **ferrous hemi-heptacarbonyl bromide**, $\text{Fe}_2(\text{CO})_7\text{Br}_4$, was also prepared. C. Chojnacky, and W. Manchot and J. Haas studied the compound formed by ferrous bromide with **ethylene**, namely, **ferrous ethylenebromide**, $\text{FeBr}_2 \cdot \text{C}_2\text{H}_4 \cdot 2\text{H}_2\text{O}$; and C. Chojnacky observed that ferrous bromide also forms a compound with **acetylene**. F. Oberhauser and J. Schormüller observed that ferrous bromide forms a compound with **cyanogen**, and also with **cyanogen bromide**, namely, $\text{FeBr}_2 \cdot \text{BrCy}$. V. Thomas said that soln. of ferrous bromide in **ethyl alcohol** yield well-formed crystals; and similarly with soln. in ether; both soln. absorb nitric oxide. Ferrous bromide is also slightly soluble in **acetic acid**; in **ethylene chloride**; and in **benzene**; but **phenol** in the cold does not attack the salt, although when warmed the salt is blackened. A. Schier, and A. Naumann and A. Schier found that ferrous bromide forms a colourless soln. with **acetonitrile**. W. Biltz and G. F. Hüttig, and F. Ephraim and R. Linn observed that ferrous bromide unites with **methylamine** forming $\text{FeBr}_2 \cdot 6(\text{CH}_3)\text{NH}_2$. R. E. Breuill prepared a complex with **ethylene-diamine**, $[\text{Fe en}_3]\text{Br}_2$. W. Hieber and co-workers studied these compounds. According to R. Müller, 100 c.c. of **pyridine** dissolve 0.49 gm. of ferrous bromide at 25° , and the complex salts with $\text{FeBr}_2 : \text{C}_5\text{H}_5\text{N} : \text{H}_2\text{O} = 1 : 5 : 0, 1 : 5 : 1, 1 : 4 : 0, 1 : 2 : 0$, and $1 : 2 : 2$ were studied by G. Spacu, R. Weinland and co-workers, and W. Hieber and co-workers. F. Blau, and A. Werner investigated the complex salt with **aa'-dipyridyl**, $[\text{Fe}(\text{C}_{10}\text{H}_8\text{N}_2)_3]\text{Br}_2 \cdot 6\text{H}_2\text{O}$, which L. A. Welo found to be diamagnetic. A. Werner found the complex $[\text{Fe}(\text{Dipyr})_3]\text{Br}_2 \cdot 6\text{H}_2\text{O}$, to be optically active. F. Blau investigated the complex salt with **aa'-phenanthroline**, and H. Freundlich and V. Birstein measured its mol. conductivity. L. Meyer and A. Scheufelen found ferrous bromide a useful catalyst in the bromination of organic compounds.

J. W. Retgers observed that no **ammonium ferrous bromide** is formed from an aq. soln. of the component salts; ferrous bromide has no influence on the crystalline form of ammonium bromide. P. A. von Bonsdorff prepared **mercuric ferric bromide**, $\text{HgBr}_2 \cdot \text{FeBr}_2 \cdot 4\text{H}_2\text{O}$, by crystallization from a soln. of the two salts. J. Kendall and co-workers obtained evidence of the formation of an **aluminium ferrous bromide**. B. Rayman and K. Preis observed that a complex

stannic ferrous bromide is formed from a mixed soln. of stannic and ferrous bromides.

The preparation of ferric bromide.—C. Löwig, and J. von Liebig prepared **ferric bromide**, FeBr_3 , by heating the residue obtained by evaporating the aq. soln.—say, a soln. of iron in an excess of bromine water—the salt collects as a sublimate. P. Höfer also obtained a sublimate of brown crystals of ferric bromide by heating ferrous bromide to 400° to 500° in the absence of air. C. Löwig prepared ferric bromide by heating ferrous bromide with bromine; and A. Scheufelen recommended heating the mixture of ferrous bromide with twice its weight of bromine in a sealed tube at 170° to 200° . F. Ephraim and S. Millmann obtained the salt by exposing powdered iron for many months to the vapour of bromine in a desiccator. C. L. Jackson and I. H. Derby observed that anhydrous ferric bromide is formed when bromine vapour acts on ferrous hexamminiodide. M. Barre obtained ferric bromide by passing the vapour of sulphur monobromide over ferric oxide at 450° to 650° . The reaction begins at 300° . O. Hönigschmid and co-workers discussed the preparation, and J. C. Hostetter and H. S. Roberts, the purification of the salt.

The hydrates of ferric bromide.—According to A. J. Balard, whilst bromine water converts hydrated ferrous oxide into hydrated ferric oxide and ferrous bromide, not a trace of ferric oxide is taken up. C. Löwig, A. E. Schaefer, J. Nicklès, A. Christensen, H. Lescœur, and L. L. de Koninck found that a soln. of ferric bromide is obtained by dissolving the anhydrous salt in water, by dissolving hydrated ferric oxide in hydrobromic acid, or by adding bromine water to a soln. of ferrous bromide. If the soln. is to contain $\text{Fe} : \text{Br} = 1 : 3$, it must not be warmed or else bromine will be evolved. The yellowish-brown soln. is darker in colour than the soln. of the corresponding chloride; it has a ferruginous taste; it gives off hydrogen bromide when evaporated, and deposits an oxybromide; it does not yield crystals when evaporated to a syrupy consistency; but when evaporated to dryness, it yields a mixture of ferric oxybromide and bromide—the latter can be separated by sublimation. According to I. Bolschakoff, if the dark brown aq. soln. be concentrated in a desiccator over sulphuric acid, it deposits the *hexahydrate*, $\text{FeBr}_3 \cdot 6\text{H}_2\text{O}$, in spherical clusters of small, dark green needles isomorphous with the corresponding hexahydrated chloride. H. Lescœur inferred from his vap. press. measurements that there are two other hydrates: *trihydrate*, $\text{FeBr}_3 \cdot 3\text{H}_2\text{O}$, and *hemitrihydrate*, $\text{FeBr}_3 \cdot 1\frac{1}{2}\text{H}_2\text{O}$.

The physical properties of ferric bromide.—C. Löwig described the anhydrous salt as a dark red, crystalline mass; and A. Scheufelen added that **crystals** of the sublimed salt furnish six-sided, rhombic plates with a metallic lustre. The salt is very deliquescent. A. Bromer gave 1.0107 for the **specific gravity** of an aq. soln. with 1.56 per cent. FeBr_3 , and 1.0641 for a soln. with 8.016 per cent. A. Scheufelen observed that ferric bromide cannot be sublimed by heat without some decomposition; and when heated in an evacuated tube, it dissociates into ferrous bromide and bromine, but ferric bromide is re-formed on cooling. The subject was discussed by G. P. Baxter, and O. Hönigschmid and co-workers. I. Bolschakoff observed that the **melting-point** of the hexahydrate is 27° , and melting occurs without decomposition. J. Nicklès, L. L. de Koninck, and I. Bolschakoff also observed that at its **boiling-point**, the aq. soln. dissociates into ferrous bromide and bromine. H. Lescœur found the **vapour pressure** of the trihydrate at 40° is about 11.9 mm., and of the hemitrihydrate, 5.5 mm. According to T. Andrews, the thermal value of the reaction $2\text{FeBr}_3 \cdot \text{Aq.} + \text{Fe} = 3\text{FeBr}_2 \cdot \text{Aq.} + 48.9$ Cals.; and since $(\text{Fe}, \text{Br}_2, \text{Aq.}) = 80.8$ Cals., the **heat of formation** is $(2\text{FeBr}_2, \text{Br}_2, \text{Aq.}) = 31.9$ Cals. J. Thomsen made observations on this subject. M. Berthelot gave $(2\text{Fe}, 3\text{Br}_{2\text{liq.}}) = 190.9$ Cals. and $(2\text{Fe}, 3\text{Br}_{2\text{gas}}, \text{Aq.}) = 212.1$ Cals.; and for the **heat of neutralization**, $[\text{Fe}_2\text{O}_{3\text{ppd.}}, 6\text{HBr}] = 33.2$ Cals. A. Scheufelen noted that heat is evolved when the anhydrous salt is dissolved in water; and T. Andrews studied the **heat of solution** of the salt.

A. Bromer gave for the **index of refraction** of aq. soln. :

	1.56 per cent. FeBr_3 (19°)			8.016 per cent. FeBr_3 (20°)	
	C-line	D-line	F-line	C-line	D-line
μ	1.33373	1.33575	1.33698	1.34518	1.34748

The **molecular refraction** of the first soln. with the μ^2 -formula is 76.11; and of the second soln., 81.07. The colour of aq. soln. of ferric bromide changes with dilution like the soln. of ferric chloride. Dil. soln. are yellow, and conc. soln. are dark brown, almost black. S. U. Pickering found that soln. with 1.0 to 0.1 gm. Fe per litre change their colour on standing until the hydrolysis has attained a stable end-state. J. S. Anderson found the **molecular extinction**, k , of soln. with C mols of FeBr_3 per litre, to be :

λ	4,340	4,860	5,470	6,020	6,770	7,100	7,880	10,620	13,000 A.
k { $C=2.0$	—	—	—	—	3.00	1.95	1.4	2.4	0.95
$C=1.0$	—	—	—	2.74	0.87	0.85	0.88	1.19	0.61
$C=0.2$	57.5	17.0	2.0	0.37	0.21	0.24	0.36	0.56	0.32

The effects of hydrolysis are not here apparent, but with soln. of conc. between 0.2 and 0.02 mol FeBr_3 per litre, the effects of hydrolysis appear. Thus, with fresh soln., and soln. six weeks old :

	$\lambda = 6530 \text{ A.}$				$\lambda = 4530 \text{ A.}$	
C	2.0	1.4	0.8	0.2	0.2	0.02
k { Fresh	5.9	1.26	0.33	0.19	31.7	11.3
Aged	4.0	0.96	0.28	0.17	29.0	27.4

Unlike soln. of ferric nitrate and sulphate, k here decreases with decreasing concentration. There is an absorption band in the ultra-red which with increasing concentration moves towards the violet. The absorption is more intense than it is with soln. of other ferric salts, and it is possible that this is due to the separation of some free bromine. This subject was discussed by R. A. Houstoun and co-workers.

N. Sasaki's observations on the **electrical conductivity** of soln. of mixtures of ferric chloride with potassium chloride and bromide indicated that the **degree of ionization** of ferric bromide is nearly the same as that of the other halides. R. Peters' observations on electrode potentials indicate that the bromide is less ionized than is the case with the chloride. R. Peters inferred that the hydrolysis of ferric bromide is greater than is that of the chloride. W. Isbekoff gave 0.92 volt for the decomposition potential of ferric bromide dissolved in molten zinc bromide. L. Riéty studied the potential difference between soln. of ferric chloride and the glass walls of a capillary containing the liquid. O. Liebknecht and A. P. Wills gave 50×10^{-6} unit for the **magnetic susceptibility** of a feebly acidic soln. of ferric chloride at 18°. A. Quartaroli said that with a feebly acidic soln. having 2.88 grms. of FeBr_3 per litre, the paramagnetism of the solute, and the diamagnetism of the solvent almost neutralize one another. Observations were also made by B. Cabrera and E. Moles.

Chemical properties of ferric bromide.—According to H. Schulze, when the vapour of ferric bromide and **oxygen** is heated to redness, ferric oxide and bromine are formed. The **hydrolysis** of a soln. of ferric bromide in **water** has just been indicated, and C. Löwig reported that a **ferric oxybromide** is formed as a residue on evaporating an aq. soln. of the salt to dryness. A. Béchamp reported an oxybromide, $\text{FeBr}_3 \cdot 7\text{Fe}_2\text{O}_3$, to be formed as a deep red soln. by leaving hydrated ferric oxide in contact with an aq. soln. of ferric bromide for three months, and $\text{FeBr}_3 \cdot 5\text{Fe}_2\text{O}_3$ to be formed by the action of silver nitrate on a soln. of ferric bromide. J. M. Ordway said that hydrobromic acid dissolves at least 5 equivalents of ferric oxide, and A. Béchamp observed that a soln. of ferric bromide dissolves hydrated ferric oxide as readily as does a soln. of ferric chloride; and C. Löwig added that a soln. of ferric bromide can dissolve at least 5 eq. of hydrated

ferric oxide. The peptization of hydrated ferric oxide by soln. of ferric bromide was also discussed by S. U. Pickering, P. Nicolardot, and A. W. Thomas and E. R. Hamburger—*vide supra*, the hydrosols and hydrogels of ferric oxide. There is here no definite evidence of the existence of an oxybromide as a chemical individual. A. Scheufelen, and E. Beckmann observed that ferric bromide is slightly soluble in **bromine**. E. C. Franklin and C. A. Kraus found that ferric bromide is slightly soluble in liquid **ammonia**; H. Hunt and L. Boneyk said that it is insoluble in liquid ammonia at 25°; and F. Ephraim and S. Millmann said that the anhydrous salt in ammonia swells up to three times its vol. forming **ferric hexamminobromide**, $\text{FeBr}_3 \cdot 6\text{NH}_3$, whose dissociation press., p mm., is:

	0°	16°	30.5°	40.2°	49°	53°
p	73	156	331	490	661	734

and the heat of dissociation is 11.2 Cals. per mol. of ammonia. V. Thomas found that **nitric oxide** is not absorbed by the anhydrous salt at ordinary temp., and when heated, the salt is reduced: $\text{FeBr}_3 + \text{NO} = \text{NOBr} + \text{FeBr}_2$; no complex with **nitrogen peroxide** is formed at ordinary temp., and at 300°, ferric oxide is formed.

A. Scheufelen found that ferric bromide is soluble in **alcohol** and **ether**; and I. Bolschakoff obtained a similar result with the hexahydrate. A. Rosenheim and P. Müller found that the salt is soluble in **acetic acid**; and G. Grünberg-Krasnowskaja studied the complex bromoacetates. A. Scheufelen investigated the action of ferric bromide on **nitrobenzene** and **nitrotoluene**; A. Schier, and A. Naumann and A. Schier showed that ferric bromide forms a blood-red soln. with **acetonitrile**; and G. Spacu, that it is reduced by **pyridine** to ferrous bromide, and it also forms a complex salt $\text{Fe}(\text{OH})\text{Br}_2 \cdot \text{C}_5\text{H}_5\text{N}$. W. Hieber and co-workers studied the pyridine compounds as well as those of **ethylenediamine**, and of **carbon monoxide**. G. A. Barbieri observed that ferric bromide forms a complex with **urea**; F. Calzolari, a complex with **antipyrine**; F. Oberhauser and J. Schormüller, with **cyanogen bromide**; P. Pistschimuka, with **methyl thiophosphate**; A. Bayer and H. Aickelin, with **tri-p-chlorotriphenyl-carbinol bromide**; and R. Fosse and L. Lesage, with **xanthylum bromide**. L. Meyer and A. Scheufelen, and L. Bruner and J. Fischler found that ferric bromide is a useful catalyst in the bromination of organic compounds.

J. Nicklès found that an aq. soln. of ferric bromide, at the temp. of a water-bath, or when exposed to sunlight, slowly dissolves **gold**, even when no excess of bromine is present. W. Isbekoff found that molten **zinc bromide** dissolves 11.57 per cent. of ferric bromide; and B. A. Isbekoff and W. A. Plotnikoff, that **aluminium bromide** forms a dark red soln. with ferric bromide, and the sp. conductivity of a 20 per cent. soln. is 0.001 mho at 150°. J. Nicklès observed that the tendency of the ferric halides to form complex salts increases with the at. wt. of the halogen. A few complex salts have been prepared. J. W. Retgers observed that no solid soln. is formed between ferric and ammonium bromides; and C. Löwig noted that if in aq. soln. a complex is formed with ammonium bromide it is readily dissociated on crystallization. P. T. Walden obtained **ammonium ferric tetrabromide**, or **ammonium tetrabromoferrate**, $\text{NH}_4\text{FeBr}_4 \cdot 2\text{H}_2\text{O}$, in deliquescent, dark green crystals, from a soln. of one part of ammonium bromide to five of ferric chloride. There is some uncertainty about the proportion of water of crystallization. The salt decomposes when it is re-crystallized from its aq. soln. No success was obtained in the attempt to prepare $(\text{NH}_4)_2\text{FeBr}_5$. When a soln. containing $\text{NH}_4\text{Br} : \text{FeBr}_3 = 2 : 1$ is crystallized, both the tetrabromoferrate and ammonium bromide crystallize from the same soln. No **potassium ferric bromide** could be prepared by C. Löwig. F. Krauss and T. von Heidelberg obtained complex salts of rubidium and caesium bromides. By crystallizing a soln. containing 5 grms. of rubidium bromide and 6 grms. of ferric bromide, P. T. Walden obtained dark green, short, doubly terminated prisms of rubidium ferric pentabromide, or **rubidium pentabromoferrate**, $\text{Rb}_2\text{FeBr}_5 \cdot \text{H}_2\text{O}$. The salt is rapidly decomposed in air, and

on re-crystallization from its aq. soln. The analogous **cæsium ferric pentabromide**, or *cæsium pentabromoferrate*, $\text{Cs}_2\text{FeBr}_5 \cdot \text{H}_2\text{O}$, was obtained from a soln. of equal proportions by weight of the component salts. It resembles the rubidium salt but it is comparatively stable. A soln. of cæsium bromide with twice its weight of ferric bromide furnishes dark green, slender needles of **cæsium ferric tetrabromide**, or *cæsium tetrabromoferrate*, CsFeBr_4 . No **sodium ferric bromide** was prepared by C. Löwig. R. F. Weinland and H. Schmid prepared **antimony ferric octodecachloride**, $\text{Fe}(\text{SbBr}_6)_3$, or $\text{FeBr}_3 \cdot 3\text{SbBr}_5$.

According to C. Lenormand, bromine acts very slowly on anhydrous ferrous chloride at the ordinary temp., combination being incomplete even after a month. In sealed tubes at about 100° , the result varies with the proportion of bromine employed. If the chloride and the bromine are mixed in the proportions $2\text{FeCl}_2 : \text{Br}_2$, combination takes place, but no crystals are formed; if, however, the bromine is in excess, **ferric dichlorobromide**, FeCl_2Br , separates in volatile crystals which are insoluble in an excess of bromine. Again, when bromine is added to ferrous chloride soln., combination takes place with development of considerable heat, and, after expulsion of the excess of bromine, the composition of the liquid agrees with the formula FeCl_2Br . The soln. is very deep red when concentrated, and yellow when dilute. It has an acidic reaction, and contains colloidal ferric oxide. It separates in volatile crystals which are insoluble in excess of bromine. The crystals are lustrous, and very dark coloured, green by reflected light, and completely opaque even in thin sections. They seem to be hexagonal tables. The compound is very deliquescent, and very soluble in water; it also dissolves readily in alcohol or ether, and, by means of the latter, can be separated from ferrous chloride. Chloroform, benzene, and toluene also dissolve it, but carbon bisulphide dissolves only a trace. It is easily decomposed by heating, but sublimes readily when heated in a tube containing a slight excess of bromine.

F. Krauss and T. von Heidlberg prepared a series of mixed salts by the action of ferric chloride or bromide on various alkali hydrides in soln. acidified strongly with the corresponding halogen acid. In this way, they prepared **rubidium ferric dichlorotribromide**, $\text{Rb}_2[\text{FeBr}_3\text{Cl}_2(\text{H}_2\text{O})]$; **rubidium ferric trichlorodibromide**, $\text{Rb}_2[\text{FeCl}_3\text{Br}_2(\text{H}_2\text{O})]$; **cæsium ferric dichlorotribromide**, $\text{Cs}_2[\text{FeBr}_3\text{Cl}_2(\text{H}_2\text{O})]$; **cæsium ferric trichlorodibromide**, $\text{Cs}_2[\text{FeBr}_2\text{Cl}_3(\text{H}_2\text{O})]$; **triethylammonium ferric chlorotribromide**, $\text{HN}(\text{C}_2\text{H}_5)_3[\text{FeClBr}_3]$, melting at 39.5° with decomposition; **triethylammonium ferric trichlorobromide**, $\text{HN}(\text{C}_2\text{H}_5)_3[\text{FeCl}_3\text{Br}]$; and **pyridinium trichlorobromide**, $\text{C}_5\text{H}_5\text{NH}[\text{FeCl}_3\text{Br}]$, melting at 84° . E. A. Dancaester studied the formation of **ferric trichlorohexabromide**, FeCl_3Br_6 , in non-aqueous soln.

F. Oberhauser and J. Schormüller treated ferrous bromide for a long time with an excess of cyanogen bromide and obtained a complex $\text{Fe}_3\text{Br}_8\text{Cy}_2 \cdot 3\text{CyBr}$; when this salt is heated between 160° and 200° , it forms **ferrosic bromide**, Fe_3Br_8 , with a dissociation press. of 12 mm. at 100° . The complex is formulated on A. Werner's co-ordination scheme, $\text{Fe}''[\text{Fe}'''\text{Br}_4]_2$, and the hexahydrate, $[\text{Fe}''(\text{H}_2\text{O})_6][\text{Fe}'''\text{Br}_4]_2$. H. Chandra obtained yellow, trigonal crystals of the *decahydrate*, $\text{Fe}_3\text{Br}_8 \cdot 10\text{H}_2\text{O}$, by dissolving hydrated ferrosic oxide in well-cooled, saturated hydrobromic acid, and evaporating the soln. below 5° , over sulphuric acid and lime. The *hexahydrate*, $\text{Fe}_3\text{Br}_8 \cdot 6\text{H}_2\text{O}$, was prepared by A. Höhn, and R. Weinland and co-workers—A. Höhn, and H. Holtmeier—in dark red, deliquescent crystals, by dissolving hydrated ferric oxide in the theoretical quantity of hydrobromic acid, and evaporating the soln. on a water-bath. The salt is blackened in light. If sodium acetate be added to the dark red soln. of ferrosic bromide, a complex ferrosic acetate is precipitated. R. Weinland with H. Holtmeier, and with A. Höhn, prepared complex salts in which the ferrous salt was replaced by salts—acetates, propionates, benzoates, etc.—of other bivalent metals—nickel, cobalt, manganese, magnesium, zinc, and cadmium. F. Oberhauser and J. Schormüller prepared complexes with cyanogen bromide, $\text{Fe}_3\text{Br}_8 \cdot 4\text{CyBr}$; with hydrogen cyanide, $\text{Fe}_3\text{Br}_8 \cdot 5\text{HCy}$; and with cyanogen, $\text{Fe}_3\text{Br}_8 \cdot n\text{Cy}_2$.

P. T. Walden found that when the attempt was made to prepare a complex of potassium and ferric bromides, from a soln. of potassium bromide with five times its weight of ferric bromide, a green salt, **potassium ferrosic bromide**, $\text{KBr} \cdot \text{FeBr}_2 \cdot 2\text{FeBr}_3 \cdot 3\text{H}_2\text{O}$, separated out in dark green, opaque, cubic crystals which gave a black hydroxide when treated with ammonia. The analogous **rubidium ferrosic bromide**, $\text{RbBr} \cdot \text{FeBr}_2 \cdot 2\text{FeBr}_3 \cdot 3\text{H}_2\text{O}$, separated in dark green, opaque, rhombohedral crystals from a soln. of rubidium bromide with five times its weight of ferric bromide. Ammonium, and the other alkalies did not form an analogous salt.

§ 39. The Iron Iodides

J. L. Gay Lussac,¹ and H. Davy noted that iodine readily unites with iron, with a slight evolution of heat, forming a brown mass which fuses at a red-heat and volatilizes at a higher temp. J. D. Smith first analyzed and established the individuality of **ferrous iodide**, FeI_2 . G. S. Sérullas prepared the anhydrous salt by passing the vapour of iodine and steam through a red-hot iron tube filled with charcoal. In 1861, L. Carius and J. A. Wanklyn prepared ferrous iodide by rapidly heating to redness iron turnings in a covered porcelain crucible, and frequently adding small quantities of iodine. The iron was initially mixed with a little iodine to drive out the air. The excess of iodine is volatilized. As the temp. falls below redness, there is suddenly developed a quantity of iodine vapour. This phenomenon may mean that ferric iodide is stable above the critical temp. or that iodine is occluded by fused ferrous iodide in a way analogous to the absorption of oxygen by fused silver. L. Carius and J. A. Wanklyn's product was a grey, laminated mass, but C. L. Jackson and I. H. Derby have shown the product is obtained in the form of red scales if air be excluded; the grey colour is an effect produced by the absorption of moisture from the air; and they prepared the salt by passing hydrogen and iodine vapour over heated ferric oxide; and by heating clippings of iron wire in a steel bicycle tube to a bright red-heat, and passing the vapour of iodine in a stream of nitrogen through the tube. Iron wire clippings gave better results than iron turnings or fillings, or reduced iron. A smaller steel bicycle tube was slipped into the exit end of the heated tube; and the ferrous iodide, volatilized from the larger tube, condensed in the smaller tube from which it was easily removed. The exit tube from the condensing tube passed through sulphuric acid, and the iodine which collected was used again. In order to avoid the loss of iodine, M. Guichard recommended using a tube containing iron and iodine, separated by an asbestos plug. The tube was evacuated, sealed, and heated in such a manner that the iron was kept at 500° , and the iodine at 180° . Ferrous iodide is formed, and it sublimes in the form of deep red crystals. It was prepared by M. Berthelot,

W. Biltz and G. F. Hüttig, B. Köhnlein, and A. E. Nordenskjöld, from iron and hydrogen iodide, or iodine and hydrogen; by C. L. Jackson and I. H. Derby, from ferrous oxide, iodine and hydrogen; and by W. Biltz and G. F. Hüttig, C. L. Jackson and I. H. Derby, H. Lesceur, and A. T. Thomson, by dehydrating the hydrated salt. E. Filhol and J. Melliès obtained it by the action of iodine on one of the iron sulphides at 200° ; L. Hackspill and R. Grandadam, by heating a mixture of iron and sodium iodide: $\text{Fe} + 2\text{NaI} = \text{FeI}_2 + 2\text{Na}$; and by W. Hieber and G. Bader, by the photochemical decomposition of ferrous tetracarbonyl iodide. Its formation in blowpipe testing was discussed by P. Casamajor, and J. Landauer. According to C. L. Jackson and I. H. Derby, the salt can be purified by sublimation in an atmosphere of nitrogen, carbon dioxide, or hydrogen provided oxygen is excluded.

The hydrates of ferrous iodide.—In 1842, A. T. Thomson treated iron with twice its weight of iodine suspended in water, and after evaporating off the water in the presence of metallic iron contained in a flask, obtained a steel-grey, laminated mass of ferrous iodide. G. M. Beringer, M. Berthelot, F. Chemnitz, A. Dupasquier, E. Fleury, M. Kop, J. H. Long, J. D. Smith, A. T. Thomson, and F. A. Volkmann studied the subject. A soln. of ferrous iodide is obtained by digesting, in the presence of water, iron filings with three to four times its weight of iodine. J. L. Gay Lussac, C. L. Jackson and I. H. Derby, and W. Biltz and E. Birk obtained the aq. soln. by dissolving anhydrous ferrous iodide in water; much heat is evolved. Dil. soln. are colourless, and conc. soln. are green.

Hydrates of ferrous iodide of indefinite composition were reported by A. Dupasquier, G. Kerner, A. P. J. du Mênil, L. Miahle, J. Preuss, and J. D. Smith. When a red crystal of ferrous iodide is exposed to air, a white border first appears and the whole crystal becomes white; this change is soon followed by the liberation of iodine which imparts a grey or black appearance. The change from red to white is an effect of moisture, it does not occur when the iodide is confined in a dry, inert medium—e.g., carbon dioxide, dry ether, etc.—but it does occur if moisture be present. C. L. Jackson and I. H. Derby found the white product had a composition corresponding with the *dihydrate*, $\text{FeI}_2 \cdot 2\text{H}_2\text{O}$. H. Lesceur's measurements of the vap. press., p , of the dihydrate indicated that at 90° , p falls from 77 mm. to 20 mm. as the dihydrate passes to the monohydrate, $\text{FeI}_2 \cdot \text{H}_2\text{O}$; and at 160° , the monohydrate gradually forms the anhydrous salt. A hot, sat. soln. of ferrous iodide deposits green crystals of the *tetrahydrate*, $\text{FeI}_2 \cdot 4\text{H}_2\text{O}$, on cooling. According to G. Kerner, a boiling soln. deposits dark green, rhombic plates of the *pentahydrate*, $\text{FeI}_2 \cdot 5\text{H}_2\text{O}$, and sp. gr. 2.873. J. D. Smith obtained similar crystals by evaporating a soln. on the water-bath. F. A. Volkmann, however, showed that the crystals obtained by evaporating aq. soln. of ferrous iodide are the tetrahydrate, $\text{FeI}_2 \cdot 4\text{H}_2\text{O}$. These crystals melt in their water of crystallization between 90° and 98° ; have a sp. gr. of 2.873 at 12° ; and, according to J. D. Smith, when heated in air they give off water and iodine, and leave ferric oxide; they blacken when heated to 50° , but the original colour is restored on cooling. F. A. Volkmann, and H. Lesceur prepared pale yellow, needle-like crystals of the *hexahydrate*, $\text{FeI}_2 \cdot 6\text{H}_2\text{O}$, by cooling a soln. $\text{FeI}_2 + 8.5\text{H}_2\text{O}$ to -16° , or by seeding a slowly cooled soln. with a crystal of the hexahydrate. The hexahydrate fuses at 8° and decomposes into the tetrahydrate. F. A. Volkmann obtained green plates of $\text{FeI}_2 \cdot 9\text{H}_2\text{O}$, by cooling the mother-liquor from the preceding hydrate to -11° ; by seeding a soln. $\text{FeI}_2 + 10.5\text{H}_2\text{O}$ cooled to -10° with a fragment of the solid obtained by cooling a soln. $\text{FeI}_2 + 9\text{H}_2\text{O}$ to -30° . This salt is less deliquescent than the hydrates just considered; it melts between 0° and 2.5° .

The physical properties of ferrous iodide.—J. L. Gay Lussac, H. Davy, B. Köhnlein, and M. Guichard said that anhydrous ferrous iodide, when sublimed, forms plate-like crystals of a deep red colour with a brownish tint; in thicker masses the colour of ferrous iodide is nearly black. When melted and allowed to solidify, it forms a reddish-black crystalline mass with a brown tinge on the fractured surface. W. Biltz and G. F. Hüttig said that the crystals are black in

reflected, and garnet-red in transmitted light. A. Ferrari and F. Giorgi found that the crystals are of the cadmium iodide type, and the X-radiograms correspond with a unit cell with the parameters $a=4.04$ Å., and $c=6.75$ Å. Some of the older observers, C. L. Jackson and I. H. Derby, S. de Luca, A. E. Nordenskjöld, A. T. Thomson, and L. Carius and J. A. Wanklyn, said that the powder is grey or white. This, as indicated above, was shown by A. E. Nordenskjöld, and C. L. Jackson and I. H. Derby to be due to the formation of the grey dihydrate on exposure to air, and these same observers said that the crystals are six-sided plates belonging to the hexagonal system, and they are optically uni-axial. The general appearance of the crystals of the hydrates is indicated above. G. S. Sérullas' description of his product as "shining yellow crystals resembling gold filings," has not been confirmed, although ferrous bromide has a dark yellow colour with a greenish-brown tinge. W. Biltz and E. Birk gave 5.315 for the sp. gr. of the sublimed salt at $25^{\circ}/4^{\circ}$. W. Biltz said that the mol. vol. is 58.27 at 25° , and he showed that the formation of the compound from its elements is attended by an expansion. J. L. M. Poiseuille studied the rate of flow of the soln. in a capillary tube. R. Hanslian measured the lowering of the b.p. of iodine by the dissolution of iron. H. Lesceur found the vap. press., p mm., of the sat. soln.:

	50°	60°	70°	80°	90°
p	30	50	74	101	144

and for the dihydrate, $p=77, 115, 160$, and 233 mm. respectively at $90^{\circ}, 100^{\circ}, 110^{\circ}$, and 120° ; and for the monohydrate, 110 mm. at 160° . F. Ephraim and co-workers also studied the mol. vol. H. Davy, and J. L. Gay Lussac observed that the anhydrous salt melts at a red-heat. According to A. T. Thomson, the anhydrous salt melts at 177° . A. Ferrari discussed the relation between the m.p. and the space-lattice. H. Davy observed that the anhydrous salt is volatile at a high temp.; and C. L. Jackson and I. H. Derby showed that it sublimes when heated in a stream of inert gas—nitrogen, carbon dioxide, or even hydrogen—oxygen must be rigorously excluded. According to T. Andrews, the heat of formation in soln. is $(\text{Fe}, \text{I}_2, \text{Aq.})=46.4$ Cals.; J. Thomsen gave 47.65 Cals.; and M. Berthelot, 47.7 Cals., and $(2\text{Fe}, \text{I}_{2\text{gas}}, \text{Aq.})=61.3$ Cals. J. Thomsen gave $(\text{Fe}, 2\text{HI}, \text{Aq.})=21.34$ Cals. Observations were also made by P. A. Favre and J. T. Silbermann. G. Beck studied the free energy of the salt; and F. Ephraim and O. Schütz, the relation between the heat of formation and the mol. vol. A. Mosnier found that the heat of soln. of the anhydrous salt in 73 parts of water is 23.3 Cals. G. Beck, and W. Herz calculated values for the entropy and vibration frequency of FeI_2 ; and E. Rabinowitsch and E. Thilo studied the heat of formation. W. Hieber and A. Woerner gave $(\text{Fe}, \text{I}_2)=30.12$ Cals.; and W. Hieber and E. Levy studied the lattice energy of the crystals.

A. K. Chapman studied the emission spectrum of anhydrous ferric iodide, and also of the aq. soln. D. J. P. Berridge obtained photographic prints with paper saturated with ferrous iodide, but the sensitivity was less than with other soluble iodides. M. Padoa and N. Vita found that under the influence of pulsating radiations of wave-lengths $670.8, 587$ to $589.6, 535$, and 460.7 Å., corresponding with quanta of $42.51, 48.57$ to $48.35, 53.30$, and 61.9 calcs. respectively, the reaction $2\text{FeI}_2 + \text{I}_2 \rightarrow 2\text{FeI}_3$ gave the following relative maximal yields: $1.40, 1.60, 1.70$, and 2.15 . This shows that the greater the light quanta, the higher the yield. A minimum of 30 calcs. is necessary to start the reaction, and the yields are then proportional to the quanta. The curves showing the relation between the yields with intermittent or continuous light indicate frequent periodic oscillations for light of short wave-length, and similar periods of somewhat less frequency for light of longer wave-length. The oscillations are explained by assuming the existence of active mols. which are the seat of adiabatic transformations and the period of existence of which appears to be the longer, the higher are their energy levels. N. Sasaki and K. Nakamura measured the potential of mixed soln. of $\text{Fe}^{++}/\text{Fe}^{+++}$.

and of I/I' , and found it to be influenced solely by the concentration of the iodide and free iodine. They also studied the Becquerel effect with these soln. M. Faraday found that the anhydrous salt is paramagnetic. O. Liebknecht and A. P. Wills gave 42×10^{-6} mass unit for the magnetic susceptibility of a soln. of ferrous iodide at 18° . L. Pauling and M. L. Huggins studied the magnetic properties. A. Schükareff observed a magnetochemical effect when, in the electrolysis of a soln. of ferrous iodide, the anode is in a magnetic field.

The chemical properties of ferrous iodide.—According to C. L. Jackson and I. H. Derby, ferrous iodide can be sublimed in an atm. of **hydrogen** without change, and the result is similar when hydrogen is passed through molten ferrous iodide, or when a mixture of hydrogen and ferrous iodide vapour is passed over iron. Hydrogen can also be bubbled through an aq. soln. of ferrous iodide without a reduction of the salt. According to H. Schulze, and C. L. Jackson and I. H. Derby, anhydrous ferrous iodide is very susceptible to oxidation, so that when heated in **air**, even at a moderate temp., all the iodine passes off in violet fumes and a residue of ferric oxide is formed which retains the shape of the iodide crystals. B. Köhnlein said that the crystals of ferrous iodide are very deliquescent; W. Biltz and E. Birk did not find them particularly deliquescent. C. L. Jackson and I. H. Derby's observations are indicated above in connection with the dihydrate. H. Lescœur said that the salt can be preserved in dry air, but C. L. Jackson and I. H. Derby reported that the decomposition of ferrous iodide by the oxygen of the air takes place at ordinary temp., for when confined in a desiccator, it soon colours the confined atmosphere purple. This subject was discussed by A. T. Thomson, and S. de Luca. According to J. Preuss, when the powdered hydrate of ferrous iodide is kept for four months in a stoppered bottle, it becomes covered with a film of iodine, and afterwards, it is but partially soluble in **water** since it forms a dark brown soln. and leaves a residue of ferric oxide. According to A. Dupasquier, M. Kop, A. P. J. du Mênil, C. L. Jackson and I. H. Derby, and O. van Schoor, the aq. soln. is colourless or bluish-green; it oxidizes easily in air precipitating yellowish-brown hydrated ferric oxide, or a basic iodide, and liberating iodine; according to J. J. Berzelius, J. Preuss, and J. D. Smith, the soln. can be evaporated without oxidation only in an atmosphere of an inert gas—and the soln. gives with water a precipitate of hydrated ferric oxide and iodine. C. F. Schönbein studied the oxidation of the compound in the presence of mercury. F. A. Volkmann said that the oxidation of the aq. soln. is accelerated by free iodine. According to G. Kerner, and L. Miahle, when the aq. soln. is concentrated in a retort until it froths up and assumes the consistency of oil, it solidifies, on cooling, to a greenish-black, crystalline mass, which is readily oxidized. R. Phillips assumed that in the decomposition of a soln. of ferrous iodide, hydriodic acid is first formed, and the decomposition of that acid produces iodine. J. H. Long estimated from the effect of $0.5N\text{-FeI}_2$ on the inversion of cane-sugar that the degree of hydrolysis of the aq. soln. was 0.078 per cent. According to C. Frederking, the tendency to oxidation may be almost wholly prevented by adding twice as much sugar as iodine, and evaporating the soln. to the consistency of a syrup. C. F. Möhr, G. Kerner, H. and T. Smith, and W. Onion recommended a similar process. The *liquor ferri iodidi* and *syrupus ferri iodidi* of the pharmacopœia are colourless soln. of iron wire in iodine water. In the latter case the soln. is mixed with glucose. The soln. is used only when freshly prepared on account of its tendency to change by oxidation. The preservation of the aq. soln. from oxidation by additions of sugar, honey, glycerol, hypophosphorous acid, etc., was discussed by W. C. Alpers, H. V. Vrný and co-workers, G. M. Beringer, P. Bohrisch, A. Dupasquier, M. Geiseler, H. Hager, A. Oberdörffer, R. H. Parker, and A. T. Thomson. According to P. Squire, if a coil of iron wire be placed in a soln. of ferrous iodide, hydrated ferric oxide is precipitated, but iodine is not liberated. According to C. Weltzien, the aq. soln. of ferrous iodide is decomposed by **hydrogen dioxide** with the separation of iodine and the formation of hydrated ferric oxide. C. F. Schönbein found that **ozone**

mixed with air reacts at once with the soln. forming hydrated ferric oxide and iodine. If potassium carbonate be added to a soln. containing three mols of ferrous iodide, and two of iodine, hydrated ferrous and ferric oxides are precipitated, and potassium iodide remains in soln. It has been suggested, without proof, that the original soln. contained Fe_3I_8 .

According to C. L. Jackson and I. H. Derby, although so susceptible to oxidation, ferrous iodide resists the action of reducing agents to a marked degree. A soln. of ferrous iodide dissolves **iodine**—*vide infra*, ferric iodide. C. F. Schönbein found that **sulphur dioxide** added to an aq. soln. of ferrous iodide makes it yellow, and the colour disappears on heating, or on adding aq. ammonia or alkali lye. H. Davy observed that when anhydrous ferrous iodide is exposed to dry **ammonia**, the gas is absorbed, and C. L. Jackson and I. H. Derby added that between 0° and 100° , a voluminous white powder, **ferrous hexamminoiodide**, $\text{FeI}_2 \cdot 6\text{HN}_3$, is formed. The compound was also prepared by F. Ephraim. W. Biltz and G. F. Hüttig cooled the iodide with a mixture of alcohol and solid carbon dioxide whilst the absorption of ammonia was in progress. W. Hieber and G. Bader prepared the hexammine by passing ammonia over ferrous tetracarbonyl iodide. W. Biltz and G. F. Hüttig, and E. Weitz and H. Müller obtained the impure hexammine by the action of ammonium iodide on an ammoniacal soln. of ferrous hexamminoacetate, and by passing ammonia into a soln. of ammonium and ferrous iodides. E. Weitz and H. Müller found that the salt prepared by the wet process furnishes pale green octahedra; the product obtained by the dry process is a voluminous white powder. W. Biltz added that like the hexammines of the other ferrous halides, the crystals are cubic, with a space-lattice having the parameter $a = 10.99 \text{ \AA}$, and the arrangement of the atoms of iron, and iodine, and the ammonia molecules is analogous to that of the hexamminochloride. G. B. Naess and O. Hassel studied the sphere of action of the anion. W. Biltz and E. Birk found that the sp. gr. is 2.052 at $24^\circ/4^\circ$; and W. Biltz added that there is an expansion of 2.44 vols. when the hexammine is formed from ferrous iodide. The dissociation press., p mm., was measured by F. Ephraim, and W. Biltz and G. F. Hüttig with the result that:

	112°	125°	135.5°	145.5°	156.5°	164°	172.5°	180.5°	187.5°
p	62	88	115	180	276	355	477	625	800

The results are plotted in Fig. 602. W. Biltz said that the dissociation press. is 150 mm. at 135° . F. Müller gave 50° to 182° for the dissociation temp. G. Beck gave 800 cal. for the heat of formation. W. Biltz, and W. Biltz and G. F. Hüttig gave for the heat of formation ($\text{FeI}_2 \cdot 6\text{NH}_{3\text{gas}}$) = 98.94 Cals., or 16.5 Cals. per mol of ammonia; or ($\text{FeI}_2 \cdot 2\text{NH}_3 \cdot 4\text{NH}_{3\text{gas}}$) = 58.0 Cals., or 14.50 Cals. per mol of ammonia. Observations were also made by F. Ephraim. W. Biltz showed that the free energy of the reaction $\text{FeI}_2 + 6\text{NH}_{3\text{gas}} = \text{FeI}_2 \cdot 6\text{NH}_3$, at 27° , and atm. press., is 42.06 Cals., or 7.01 Cals. per mol of ammonia; and that the hexammine is a cation ammine which indicates that the structural formula is $[\text{Fe}(\text{NH}_3)_6]\text{I}_2$. F. Ephraim found that the hexammine retains its white colour in air, and is sensitive to light only when it loses ammonia. C. F. Jackson and I. H. Derby reported that the hexammine decomposes rapidly with the liberation of ammonia when it is exposed to air, but it remains unchanged in an atm. of ammonia, even at 100° ; it loses ammonia when heated in an indifferent gas, and forms a dark brown powder, of unknown composition—but contains 2 or 3 mols. of ammonia—which is stable in air; when exposed to the vapour of bromine, a large proportion, 70 to 71 per cent., is absorbed, and a mixture of ammonium ferric bromide, and

FIG. 602.—The Dissociation Pressures of the Ferrous Amminoiodides.

ferrie ammonium pentabromiodide, $\text{NH}_4\text{FeIBr}_5$, is formed. W. Biltz and G. F. Hüttig showed that when the hexammine is heated at about 153° , it passes into **ferrous diamminiodide**, $\text{FeI}_2 \cdot 2\text{NH}_3$, but no **ferrous monamminiodide** is formed. The dissociation press. of the diammine was found by W. Biltz and G. F. Hüttig to be 6.1, 12.1, and 85.4 mm. respectively at 215° , 231° , and 278° ; and W. Biltz gave 100 mm. at 287° . F. Müller gave over 350° for the dissociation temp. of the diammine. W. Biltz and G. F. Hüttig found the heat of formation is $(\text{FeI}_2 \cdot 2\text{NH}_{3\text{gas}}) = 40.92$ Cals., or 20.46 Cals. per mol of ammonia. W. Biltz observed that the free energy of the reaction $\text{FeI}_2 + 2\text{NH}_{3\text{gas}} = \text{FeI}_2 \cdot 2\text{NH}_3$, at 27° , and atm. press., is 21.46 Cals., or 10.73 Cals. per mol of ammonia; unlike the hexammine, the salt is not co-ordinative, and is regarded as a double salt. W. Hieber and E. Levy, and G. L. Clark studied the stabilities of the ammines. F. W. Bergstrom observed that no definite products are formed by the action of an ammonia soln. of potassium amide on ferrous iodide.

When a soln. of iodine and iron pentacarbonyl in dry ether is evaporated, W. Hieber and co-workers found that dark brown plates of **ferrous tetracarbonyl iodide**, $\text{Fe}(\text{CO})_4\text{I}_2$, are formed; and H. Hock and H. Stuhlmann prepared it by the action of $\text{Fe}(\text{CO})_4\text{Hg}$ on a soln. of iodine in carbon disulphide. W. Hieber said that the salt is decomposed below 750 mm. at 75° into ferrous iodide and carbon monoxide. W. Hieber and co-workers found that the mol. wt. in nitrobenzene soln. is 430.4—theory for $\text{Fe}(\text{CO})_4\text{I}_2$, 421.3; the salt in nitrobenzene soln. slowly decomposes in sunlight; it is decomposed by water forming a soln. of ferrous iodide with the evolution of carbon monoxide; it forms complex salts, $\text{FeCO}(\text{C}_5\text{H}_5\text{N})_2\text{I}_2$, and $\text{Fe}(\text{CO})_2(\text{C}_5\text{H}_5\text{N})_2\text{I}_2$, with pyridine. C. L. Jackson and I. H. Derby observed that ferrous iodide is reduced when it is heated to redness in **ethylene**, or in **acetylene**. J. W. Retgers found it to be almost insoluble in **methylene iodide**. F. Ephraim and R. Linn observed that ferrous iodide forms a complex with **methylamine**, $\text{FeI}_2 \cdot (\text{CH}_3 \cdot \text{NH}_2)_6$; H. M. Elsey, a complex with **ethylamine**, but it is insoluble in ethylamine, and soluble in **dimethylaminé**. R. E. Breuill, and W. Hieber and co-workers prepared a complex with **ethylenediamine**, $[\text{Fe en}_3]\text{I}_2$. C. L. Jackson and I. H. Derby observed that a complex is formed with **aniline**; H. Grossmann and F. Hünseler, a complex with **phenylhydrazine**, $\text{FeI}_2(\text{C}_6\text{H}_5 \cdot \text{NHNH}_2)_6$; W. Hieber and co-workers, R. Weinland and co-workers, G. Spacu, and H. Hock and H. Stuhlmann, complexes with **pyridine**, $\text{FeI}_2(\text{C}_5\text{H}_5\text{N})_6$, $\text{FeI}_2(\text{C}_5\text{H}_5\text{N})_4$, and $\text{FeI}_2(\text{C}_5\text{H}_5\text{N})_2$; F. Blau, and A. Werner, a complex with $\alpha\alpha'$ -**dipyridyl**, $[\text{Fe}(\text{C}_{10}\text{H}_8\text{N}_2)_3]\text{I}_2 \cdot 5\text{H}_2\text{O}$; and it is optically active; and F. Blau, a complex with $\alpha\alpha'$ -**phenanthroline**. C. L. Jackson and I. H. Derby found that ferrous iodide is soluble in **alcohol**. V. Thomas added that the alcoholic soln. absorbs nitric oxide. C. L. Jackson and I. H. Derby found ferrous iodide to be soluble in **glycerol**, and soln. of **sugar**. J. H. Long said that cane-sugar is inverted by ferrous iodide soln. T. Salzer, and A. Dupasquier studied the action of ferrous iodide on **starch**, and **cellulose** or filter paper. C. L. Jackson and I. H. Derby found that no perceptible chemical reaction occurs with **ether**; according to L. B. Parsons, ferrous iodide is insoluble in **carbon tetrachloride**, **carbon disulphide**, **chloroform**, **quinoline**, **pyridine**, **heptane**, **ethylbenzene** and **benzene**, and a little soluble in **alcohol**, **ether**, and **acetone**. B. Köhnlein observed no reaction with **propyl iodide**. A. Job and R. Reich observed that an ethereal soln. reacts with **zinc ethyl iodide** forming $\text{FeC}_2\text{H}_5\text{I}$. J. R. McKee and co-workers found that the soln. of ferrous iodide in **furfurol** does not conduct electricity. C. L. Jackson and I. H. Derby said that no perceptible action was observed between ferrous iodide and **benzene**, **benzyl chloride**, **phenol**, or **hydroquinone**. C. Liebermann and H. Sachse, and P. Bruck recommended ferrous iodide as a carrier of iodine in organic reactions. C. Moureau and C. Dufraisse studied its action on the oxidation of **acrolein**. G. Champetier found that the reaction with **phenyl zinc bromide** can be represented by the equation: $2\text{C}_6\text{H}_5\text{ZnBr} + 2\text{FeI}_2 \rightarrow 2\text{C}_6\text{H}_5\text{FeI} + \text{ZnBr}_2 + \text{ZnI}_2$.

C. L. Jackson and I. H. Derby found that **mercury** has no action on **ferrous**

iodide when the two are ground together, or distilled together. Molten silver reduces ferrous iodide to iron. No reduction occurs by the action of nascent hydrogen from hydriodic acid and zinc or iron. C. Wagner and W. Preiss studied the induction of the reaction between chromic acid and iodides by ferrous salts.

The complex salts of ferrous iodide.—J. W. Retgers observed that no solid soln. or compounds separate from mixed soln. of ammonium and ferrous iodides. J. F. W. Johnston observed that an auric ferrous iodide separates from a mixed soln. of auric and ferrous iodides. J. B. Berthemot obtained a mercuric ferrous iodide by cooling a hot, mixed soln. of mercuric iodide and ferrous chloride; and P. A. von Bonsdorff, by the evaporation of a soln. of mercuric and ferrous iodides. A. Duboin found that the dark orange octahedra were mercuric ferrous hexaiodide, $2\text{HgI}_2 \cdot \text{FeI}_2 \cdot 6\text{H}_2\text{O}$. The sp. gr. is 4.04 at 0° . P. A. von Bonsdorff added that his product formed yellowish-brown needles, which oxidized readily, were decomposed by water, and were soluble in acetic acid, and in alcohol. According to A. Mosnier, ferrous iodide also forms a lead ferrous hexaiodide, $\text{PbI}_2 \cdot 2\text{FeI}_2 \cdot 3\text{H}_2\text{O}$, and likewise a complex salt with platinum iodide.

The higher iodide, ferric iodide, FeI_3 , has not been isolated although it is probably contained in a soln. of ferrous iodide to which the proportion of iodine required for the tri-iodide has been added, $2\text{FeI}_2 + \text{I}_2 = 2\text{FeI}_3$. G. Kerner regarded the product as a soln. of iodine in aq. ferrous iodide because the solution gave most of the reactions of ferrous salts, and it gives a blue precipitate with potassium ferrocyanide which A. Oberdörffer showed is at first light blue, but becomes dark blue by the absorption of iodine. The precipitation of hydrated ferrous and ferric oxides by alkali hydroxide or carbonate from the mixed soln. of ferrous and ferric iodide obtained by mixing iodine and iron ($3\text{Fe} + 4\text{I}_2$) with water, is attributed to the formation of complex ions FeI_3' from the union of I' -ions with ferrous iodide molecules; and the FeI_3' -ions are stable in the presence of ferric ions. E. Fleury says that the action of iodine on iron is inappreciable if the temp. be kept below 15° , but if the mixture be heated, ferric oxide is formed. A large excess of iodine is required to dissolve all the iron, and a large excess of iron is needed to convert the iodine into ferrous iodide. E. Fleury suggested that ferric iodide is first formed, and this is decomposed by heat into ferric oxide and hydriodic acid which then reacts with free iron to form ferrous iodide. G. Kerner showed that hydriodic acid dissolves recently-precipitated ferric hydroxide; the soln. smells of iodine, and gives the reactions characteristic of a ferrous salt and free iodine. The reaction is presumably: $\text{Fe}_2\text{O}_3 + 6\text{HI} = 3\text{H}_2\text{O} + 2\text{FeI}_2 + \text{I}_2$; but J. Nicklès showed that if the ferric hydroxide be dissolved by hydriodic acid in the presence of ether, it does not give the reaction of a ferrous salt with potassium ferricyanide for some time. J. L. Lassaigne showed that the resulting yellowish-red soln. is resolved by heat into ferrous iodide and free iodine; and P. Squire, that although a soln. of ferrous iodide deposits ferric hydroxide when exposed to the air, the reaction is not analogous with that of the corresponding chloride: $12\text{FeCl}_2 + \text{Aq.} + 3\text{O}_2 = 8\text{FeCl}_3 + 4\text{Fe}(\text{OH})_3$, because the liquid still gives the reactions of a ferrous and not of a ferric salt. The subject was also discussed by J. J. Berzelius, J. M. Ordway, W. Spring, P. Nicolardot, J. Reitstötter, J. H. Mathews, H. Grossmann and F. Hünsele.

According to R. Abegg, and W. Maitland, the equilibrium constant of the reaction: $2\text{Fe}^{++} + 2\text{I}^- \rightleftharpoons 2\text{Fe}^{+} + \text{I}_2$ is $[\text{Fe}^{+}][\text{I}^-] = 0.00023[\text{Fe}^{++}]$ in the presence of solid iodine, so that when a ferric salt is treated with an alkali iodide, virtually all the iron in the solute forms iodine and ferrous iodide; the ferric iodide can be stable only in the presence of an enormous excess of ferrous iodide. K. Lialikoff and M. Bela found that the equilibrium depends on the degrees of ionization of the ferric, ferrous, and potassium iodides, but this effect becomes less important if the reaction takes place in 0.5*N*-potassium iodide soln. The equilibrium constant is profoundly changed by the presence of an acid, the extent of the alteration varying but slightly with the conc. of the acid. The equilibrium is displaced somewhat to

the right by the presence of either glycerol or methyl alcohol in 30 per cent. conc. The reaction was studied by J. N. Brönsted and K. Pedersen, and H. M. Dawson and E. Spivey; and E. K. Rideal and E. G. Williams studied the photochemical equilibrium. N. Sasaki added a soln. of barium iodide to one of ferric sulphate and observed that ferric iodide primarily formed decomposes rather slowly so that the freshly-prepared soln. is mainly one of ferric iodide. The electrical conductivity of the fresh soln. is nearly as great as a soln. of ferric chloride or bromide of the same concentration. The equilibrium is displaced in favour of ferric iodide by exposure to light. J. N. Brönsted and K. Pedersen studied the reaction between ferric chloride and potassium iodide at 25°, and obtained results in accord with the law of mass action for ionic equilibria. N. Sasaki represented the reaction: $\text{Fe}^{+++} + \text{I}^- = \text{FeI}^{++}$; $\text{Fe}^{+++} + 2\text{I}^- = \text{FeI}_2^+$; $\text{FeI}^{++} = \text{Fe}^{+++} + \text{I}^-$; $\text{FeI}_2^+ = \text{Fe}^{+++} + \text{I}^- + \text{I}^-$; and $\text{I} + \text{I} = \text{I}_2$, and A. von Kiss and I. Bossanyi found that on these assumptions, the reaction is unimolecular with respect to the ferric ions; and bimolecular for the iodine-ions. The hydrolyzed ferric-ions do not act with a measurable speed. The reaction is said to be ionic up to a concentration 0.15, and to obey the rule for neutral salts. Of the alkali iodides, only the sodium salt exerts a specific action. The chlorides of the uni- and bi-valent metals exert no marked influence; ferrous ions and sulphate ions slow down the reaction, whilst H^- , NO_3^- , Br^- , and ClO_3^- ions catalyze the action feebly.

G. B. Kistiakowsky found that the reaction $2\text{Fe}^{+++} + \text{I}_3^- = 2\text{Fe}^{+++} + 3\text{I}^-$ is sensitive to radiations $\lambda = 5460, 4360, \text{ and } 3660 \text{ \AA.}$ in the mercury spectrum; and E. K. Rideal and E. G. Williams observed that the reaction $2\text{Fe}^{+++} + \text{I}_2 \rightleftharpoons 2\text{Fe}^{+++} + 2\text{I}^-$ is photosensitive to both ultra-violet and visible light, the latter within the range 5500 to 6500 \AA. , with an apparent maximum at 5800 \AA. The triiodide ion is the photosensitive constituent and the energy of excitation is equivalent to 2.14 volts, almost identical with the resonance potential of the iodine molecule. One quantum of absorbed radiant energy causes 1 mol. of iodine to react. The dark equilibrium constant, $(\text{Fe}^{+++})(\text{I}_2)^{1/2}/(\text{Fe}^{+++})(\text{I}^-)$, is 23.6 at 25°. The ratio of the velocity constant of the liberation of iodine at 35° to that at 25° is 2.713, whilst for the photochemical reaction this ratio is 1.17. The addition of potassium chloride increases the thermodynamic concentrations of all the reactants, increasing the velocity of the reaction thereby, but not affecting the final equilibrium.

C. F. Möhr's observations that a very dil. soln. of ferric chloride (1 in 12,300) gives a blue colour on the addition of starch and potassium iodide only after a considerable time, depends on the fact that a soln. so much diluted is almost completely hydrolyzed and therefore only a very small proportion of iron can be present in the form of ferric ions; and the slow development of the blue coloration, owing to the formation of free iodine, is due to the reaction between the I^- ions and the Fe^{+++} ions from the hydroxide.

M. Berthelot gave for the heat of formation of ferric iodide ($2\text{Fe}, 3\text{I}_{2\text{soln.}}, \text{Aq.}$) = 98.5 Cals.; ($2\text{Fe}, 3\text{I}_{2\text{gas}}, \text{Aq.}$) = 139.1 Cals.; and $(\text{Fe}_2\text{O}_{3\text{ppd.}}, 6\text{HI}) = 33.2 \text{ Cals.}$ Observations were made by T. Andrews. The subject was studied by E. Rabino-witsch and E. Thilo. A. K. Chapman measured the emission spectral lines of ferric iodide. L. Riéty measured the potential of soln. entering and leaving a capillary tube. E. Beckmann estimated from the effect on the b.p. of iodine that ferric iodide is present in iodine soln. in doubled molecules, Fe_2I_6 ; J. Timmermans, and E. Beckmann's observations on the effect of the salt on the f.p. of iodine were unsatisfactory because of the low solubility of the salt. L. Carius and J. A. Wanklyn found that when a mixture of ferrous iodide and iodine is heated to the temp. at which iodine is evolved, then, on cooling, a temp. is attained at which iodine is copiously evolved. W. Manchot and O. Wilhelms said that in the reaction between potassium iodide, hydrogen dioxide, and ammonium ferrous sulphate, an **iron pentaiodide**, FeI_5 , is formed as a transient intermediate compound. J. Nickles obtained what he regarded as ferric iodide by the action of hydriodic acid in ethereal soln. on ferrous iodide, and noted that the soln. dissolves metallic gold. E. C. Franklin

and C. A. Kraus say that ferric iodide (probably ferrous iodide) is very soluble in liquid ammonia. P. T. Walden did not succeed in preparing complex salts of ferric iodide with other metal iodides. K. Jablczynsky and M. Stückgold examined the reaction between ammonium ferrous iodide and iodine, and found that combination occurs to the extent of 72 per cent. at ordinary temp.; and the speed of reaction is 4.5 times as great as the reverse reaction—decomposition of ferric iodide. This is taken to mean that the iodometric titration of ferric iron is inaccurate.

K. Seubert and A. Dorrer found that a mixture of dil. soln. of ferric chloride and potassium iodide give a yellowish-brown coloration, much deeper than a soln. of ferric chloride of corresponding concentration, and they assume that an unstable **ferric dichloriodide**, FeICl_2 , is formed: $\text{FeCl}_3 + \text{KI} \rightleftharpoons \text{FeICl}_2 + \text{KCl}$, and that a neutral aq. soln. of ferrous chloride and alcoholic iodine owes its brownish-red colour to the same compound. It is not ferric hydroxychloride, $\text{FeCl}_2(\text{OH})$, because the soln. deposits iodine when diluted with water. For **ammonium ferric pentabromiodide**, $\text{NH}_4\text{FeBr}_5\text{I}$, *vide supra*.

§ 40. The Iron Sulphides—Ferrous Sulphide and Pyrrhotite

The *pyrites fuscus lamellosus* of J. G. Wallerius¹ was called by J. B. L. Romé de l'Isle *pyrites* or *marcassites rhomboïdales*, and he described the hexagonal crystals. A. G. Werner called it *Magnetkies*; R. Kirwan, *magnetic pyrites*; W. Phillips, *magnetic iron pyrites*; R. J. Haüy, *fer sulfuré magnétique*—vulgairement *pyrite magnétique*; C. C. Leonhard, *Leberkies*; F. S. Beudant, *Leberkise*; W. Haidinger, *pyrrhotin*—from *πυρρός*, reddish; and J. D. Dana, *pyrrhotite*. The iron sulphide found in meteorites and named by W. Haidinger *troilite*—after D. Troili—is considered by G. Linck, S. Meunier, and others to be pyrrhotite. Both forms are ferrous sulphides containing a small excess of sulphur in solid soln., and, as emphasized by G. A. Kenngott, and T. Petersen, their principal difference is in their magnetic properties. D. Forbes described a nickeliferous variety which M. F. Heddle called *inverarite*—from its occurrence in Inverary, Argyleshire; D. Forbes named a variety from the eastern slope of the Andes *kræberite*—after P. Kræber; and A. Knop, called a variety from Horbach, in the Black Forest, *horbachite*. C. W. Blomstrand described a variety from Nya-Kopparberg, Sweden, and he called it *Vallerite* or *Wallerite*—after J. G. Wallerius; J. Petréń regarded it as a mixture of different minerals. As indicated below, pyrrhotite contains a variable proportion of sulphur. To summarize, if pyrrhotite be included in the general term *pyrites*:

PYRITES	cubic crystals	pyrite
	rhombic crystals	marcasite
	rhombohedral crystals—magnetic	pyrrhotite

The nature of ferrous sulphide and of the pyrrhotites.—According to E. T. Allen² and co-workers, "pure ferrous sulphide has never been made," except, presumably, by chance. Analyses of pyrrhotite were reported by A. Hilger, M. Toumaire, T. Scheerer, A. Raimondi, H. How, B. J. Harrington, F. Ehrenheim, and numerous others. The nickel and cobalt contents of pyrrhotite were discussed by C. W. Dickson, H. Schneiderhöhn, E. Weinschenk, M. F. Heddle, D. Forbes, J. D. Dana, and W. Campbell and C. W. Knight.

The analyses of pyrrhotite show a more variable ratio for Fe : S than is the case with the other forms of iron sulphide. Thus, F. Stromeyer gave Fe_3S_4 , for the composition of a sample from Barèges. T. Sidot's synthesis of this **ferrosic sulphide**, Fe_3S_4 , analogous to magnetite, Fe_3O_4 , indicated below, is questioned by C. Fontana, and W. F. de Jong and H. W. V. Willems. A. Stelzner gave Fe_4S_5 , for the composition of a sample from Himmelstürst, Freiberg; while samples analyzed by F. Stromeyer, H. V. Regnault, P. Berthier, C. F. Rammelsberg, I. Domeyko, and E. Manasse corresponded with Fe_5S_6 ; C. F. Plattner, C. F. Rammelsberg, T. Petersen, and G. Lindström gave results agreeing with Fe_6S_7 ; J. Akermann, C. F. Rammelsberg, G. Lindström, H. Hahn, H. Habermehl, A. Funaro, A. Stelzner, W. Irmer, G. Rose, J. J. Berzelius, G. Nyiredy, and W. J. Sharwood, with Fe_7S_8 ; K. Bornemann and O. Hengstenberg, H. Rose, C. F. Rammelsberg, L. Michel, P. Berthier, F. M. Baumert, G. Lindström, G. H. F. Ulrich, and J. D. Dana, with Fe_8S_9 ; E. Schumacher, C. Doelter, N. von Leuchtenberg, C. Bodewig, and M. F. Heddle, with Fe_9S_{10} ; F. von Schaffgotsch, C. F. Rammelsberg, and G. Lindström, with $\text{Fe}_{10}\text{S}_{11}$; J. Middleton, C. F. Rammelsberg, G. Lindström, C. Bodewig, L. F. Nilson, J. Thiel, J. D. Dana, F. von Schaffgotsch, M. Palfy, E. Arbeiter, A. Serra, A. Bianchi, and E. Glatzel, with $\text{Fe}_{11}\text{S}_{12}$; L. Bucca, C. Doelter, and R. Lorenz, with $\text{Fe}_{12}\text{S}_{13}$; and G. Lindström, G. A. Kenngott, C. S. Schiffner and co-workers, R. Brauns, V. Zeleny, C. Hatchett, C. W. Dickson, W. J. Sharwood, and A. Serra, with FeS . The analyses of a sample of troilite from meteorites gave S. Meunier Fe_4S_5 , Fe_6S_7 , and Fe_8S_9 ; J. L. Smith, Fe_8S_9 ; and J. L. Smith, C. F. Rammelsberg, I. Domeyko, G. Nauckhoff, F. E. Geinitz, C. Winkler, S. M. Losanitsch, J. Schilling, W. Flight, E. Cohen, O. A. Derby, W. Tassin, L. H. Borgström, and W. Ramsay and L. H. Borgström studied the subject. The analyses of artificial pyrrhotite gave J. J. Berzelius, C. F. Rammelsberg, F. Stromeyer, J. A. Arfvedson, B. G. Bredberg, A. S. Eakle, L. Bucca, C. Doelter, and R. Lorenz results ranging over Fe_2S_3 (*vide infra*), Fe_3S_4 , Fe_4S_5 , Fe_7S_8 , Fe_8S_9 , $\text{Fe}_{10}\text{S}_{11}$, $\text{Fe}_{12}\text{S}_{13}$, and FeS —*vide infra*, R. Juza and W. Biltz in connection with pyrites. They could find only FeS and FeS_2 , not the intermediate forms.

F. Stromeyer found that a residue of sulphur remained when pyrrhotite is dissolved in hydrochloric acid, and supposed that it consists of ferrous sulphide mixed with pyrites; and this view was supported by J. J. Berzelius, C. Doelter, L. Gedel, and A. Knop. M. Leo also found specimens of pyrrhotite with inclusions of pyrite; and E. Wildschrey noted a number of occurrences of pyrrhotite in the neighbourhood of deposits of pyrite. The hypothesis was condemned by the fact that F. von Schaffgotsch, G. Rose, H. Habermehl, and E. Posnjak and co-workers found that when the mineral is dissolved in acids, sulphur, not pyrites, remains; and E. Arbeiter found that pyrrhotite gives off sulphur at a higher temp. than does pyrite. F. von Schaffgotsch, E. Arbeiter, C. W. Blomstrand, G. Cesaro, and R. Scheuer favoured the assumption that pyrrhotite is a mixture of ferric sulphide, Fe_2S_3 , and ferrous sulphide, FeS . P. Niggli considered it to be a polysulphide. C. F. Plattner observed a loss of sulphur when pyrrhotite is heated in hydrogen and a residue of ferrous sulphide remained. J. J. Berzelius, and likewise also C. F. Rammelsberg, suggested that the sulphides represented by Fe_7S_8 may exist in two forms: $6\text{FeS}.\text{FeS}_2$, and $5\text{FeS}.\text{Fe}_2\text{S}_3$; whilst F. von Schaffgotsch gave $\text{FeS}.\text{Fe}_2\text{S}_3$, $5\text{FeS}.\text{Fe}_2\text{S}_3$, and $9\text{FeS}.\text{Fe}_2\text{S}_3$; and G. Rose, $5\text{FeS}.\text{Fe}_2\text{S}_3$. A. Breithaupt, M. L. Frankenheim, F. von Kobell, and T. Petersen assumed that pyrrhotite is, in the ideal case, ferrous sulphide which may be isomorphous with millerite, and nickelite. T. Sidot concluded from the production of pyrrhotite from magnetite and hydrogen sulphide that its formula is Fe_3S_4 ; C. Bodewig, E. Glatzel, and C. Doelter gave the formula $\text{Fe}_{11}\text{S}_{12}$ which was regarded as a complex $10\text{FeS}.\text{FeS}_2$,

and not $9\text{FeS} \cdot \text{Fe}_2\text{S}_3$ because of the isomorphism of pyrrhotite with wurtzite. G. Cesaro, H. Habermehl, and C. F. Rammelsberg represented pyrrhotite by $\text{Fe}_n\text{S}_{n+1}$, or $\text{Fe}_2\text{S}_3(n-2)\text{FeS}$, when the analyses ranged from Fe_5S_6 to $\text{Fe}_{16}\text{S}_{17}$. G. Cesaro assumed that the molecule contained two $\text{S}=\text{Fe}-\text{S}$ groups, so that $\text{Fe}_{11}\text{S}_{12}$ was represented by the chain formula: $\text{S}=\text{Fe}'''-\text{S}-(\text{Fe}_9''\text{S}_8)-\text{S}-\text{Fe}'''=\text{S}$.

E. Glatzel favoured the formula FeS , and he based his opinion on the results of 70 analyses, 66 of which agreed well with the formula FeS . The reviews of the analytical data by G. Lindström, and by H. Habermehl indicated that pyrrhotite is a homogeneous compound of variable composition. At that time, homogeneous solids of variable composition were anomalous. To-day, homogeneous solids of this type are fairly common and they are called solid soln. or isomorphous mixtures. F. von Schaffgotsch, C. Bodewig, and H. Habermehl showed that pyrrhotite contains no free sulphur accessible to the solvent effect of carbon disulphide. E. T. Allen and co-workers tested the hypothesis that the various pyrrhotites are solid soln. of sulphur in ferrous sulphide. They prepared various pyrrhotites by the thermal decomposition of pyrite or marcasite, or by heating iron in sulphur vapour—*vide infra*. The composition of the product formed at any temp. depends on the press. of the sulphur vapour; the maximum percentage obtained at 600° was 6.04, and by extrapolation, pyrrhotite with 6.5 per cent. of sulphur, the maximum proportion found in natural pyrrhotites, would be formed at 565° . The formula of pyrrhotite is therefore represented $(\text{FeS})_n$, or, according to P. Niggli, $n\text{FeS} \cdot m\text{S}$. F. Zambonini, J. Jakob, and W. F. de Jong and H. W. V. Willems also agreed with the view that pyrrhotite is a solid soln. of ferrous sulphide and sulphur; and the hypothesis is in harmony with the X-radiograms of C. Fontana—*vide infra*. According to L. S. Ramsdall, the excess sulphur in pyrrhotite is accompanied by a decrease in the size of the unit cell, and a lowering of the density; and these facts are taken to indicate a replacement of Fe by S, rather than an addition of more S. J. H. L. Vogt stated that when melted with the sulphides of other heavy metals, ferrous sulphide is present in soln. as simple molecules.

A number of **iron subsulphides** has been reported; thus, J. A. Arfvedson³ obtained Fe_3S , as a greyish-black powder by reducing red-hot ferric sulphate in hydrogen; J. A. Arfvedson, L. Playfair and J. P. Joule, A. Murlot, and P. Berthier, Fe_2S , by reducing ferrous sulphate in hydrogen, and by fusing a mixture of iron and ordinary iron sulphide in a graphite crucible; and A. Gautier and L. Hallopeau, L. Michel, and H. N. Warren, Fe_4S_3 , by heating iron to 1300° to 1400° in an atm. of the vapour of carbon disulphide, and cooling the product in the same atmosphere. J. B. Peel and co-workers obtained a partially-fused product of variable composition—average Fe_7S_6 . The sp. gr. of the crystalline mass was 6.96; it did not alter on exposure to air; it was oxidized with difficulty; and was soluble in dil. acids with the evolution of hydrogen and hydrogen sulphide. H. N. Warren found that if iron which has been fused with a small proportion of sulphur be made the anode, with a dil. soln. of ferrous chloride as electrolyte, then on electrolysis, iron is deposited on the cathode of copper or platinum, and in a few hours, the black, granular precipitate on the anode may be detached. It is ferrous sulphide, FeS . This is taken to mean that FeS is the only compound formed by the simple action of sulphur on metallic iron, aided by heat, and that the sulphur does not disseminate itself throughout the whole mass of metal to form a compound possessing a formula where iron predominates largely, such as would be inferred from the formula expressed by Fe_3S ; but exists rather in the form of sulphide or iron, disseminated, so to speak, through a mass of pure iron, the sulphide present forming a simple network allowing the current free passage; the iron being a much better conductor of electricity than the sulphide, becomes more rapidly dissolved, leaving the residual sulphide. E. V. Britzke and A. F. Kapustinsky, and K. Jellinek and J. Zakowsky discussed the affinity of sulphur for iron.

H. le Chatelier and A. Ziegler obtained no evidence of the formation of a subsulphide in the regulus obtained by melting together iron and ferrous sulphide.

Under the microscope, the product appears as a mixture of the two components. J. E. Stead described the microstructure of the products obtained by melting different proportions of sulphur with iron (*q.v.*). R. Scheuer observed that in some cases, the mixtures of iron and ferrous sulphide appear homogeneous, and they cannot be separated into their constituents by a magnet. Observations on the subject were also made by G. P. Schweder. W. Treitschke and G. Tammann constructed a thermal diagram for a mixture of iron and ferrous sulphide (Figs. 604 and 605); they found that ferrous sulphide and iron are not completely miscible in the fused condition, mixtures containing 8 to 80 per cent. of ferrous sulphide separating into two layers at 1400°. The f.p. curve falls from 1540°, the f.p. of iron, to 1400°, remains horizontal until the disappearance of the layer rich in iron, then falls to the eutectic temp., 970°, and finally rises to 1300°, the f.p. of ferrous sulphide. The eutectic mixture contains about 16 per cent. of the sulphide. The components separate to a great extent in the form of two sat. mixed crystals, containing 3 and 96 per cent. by weight of iron respectively. After crystallization is complete, secondary changes due to polymorphous transformations of the components take place. Pure iron shows two transition points at 855° and 760°, corresponding with the transformation of γ - to β -iron and β - to α -iron respectively; the first of these is lowered to a greater extent than the second by the presence of ferrous sulphide, and with less than 92 per cent. of iron there is only one break in the cooling curve at 800°, which is probably connected with the solubility of ferrous sulphide in γ -iron. There is some evidence to show that when the temp. of mixtures rich in iron falls to about 800°, the mixed crystals undergo partial separation into their components. At 130° occurs the transition of β FeS, observed by H. le Chatelier and A. Ziegler; it is attended by a considerable dilation. The deleterious effect of traces of sulphur on the properties of iron is discussed in the light of the above results. In mixtures containing more than 2 per cent. of sulphur, this effect is due to the presence of a readily fusible layer of sulphide between the particles of iron. That the presence of even 0.02 per cent. of sulphur is disadvantageous is to be ascribed to the brittle character of the mixed crystals rich in iron. The transformation at about 130° was investigated by F. Rinne and H. E. Boeke—*vide infra*—they said that at 138° the solid soln. has 7 per cent. of iron as a maximum, and R. Loebe and E. Becker said 1 per cent. of iron at 985°. The structure was discussed by H. Rheinboldt.

K. Friedrich obtained rather simpler results, no separation into layers was observed at 1400° with mixtures containing 8 to 80 per cent. Fe. This was confirmed by F. H. Edwards, R. Loebe and E. Becker, and B. Bogitsch, who found that the f.p. curve, Fig. 603, is simple, and has a eutectic at 985° and 84.6 per cent. FeS. Observations were made by R. Juza and co-workers. A. Fry found the solubility of sulphur in γ -iron is 0.025 per cent., and A. Ziegler gave 0.03 per cent. K. Miyazaki said that the eutectic point is at 985° and 83 per cent. FeS. The solid components on the iron side of the eutectic are virtually immiscible, whilst the ferrous sulphide retains about 1 per cent. of iron in solid soln. K. Miyazaki found for the liquidus curve:

FeS .	0	10.33	20.90	32.47	51.49	71.39	80.84	88.28	98.63 per cent.
F.p. .	1530°	1445°	1409°	1370°	1335°	1175°	1035°	1056°	1183°

FIG. 603.—Equilibrium Diagram of the System: Fe-S.

C. Benedicks and H. Löfquist's equilibrium diagram of the whole system Fe-S is shown in Fig. 604. C. Benedicks observed that a break is produced in the liquidus curve of the system Fe-FeS by the presence of a third component which is more soluble in one of the pure components than is the mixed mass. For instance, a break is produced by silicon in the liquidus curve of iron and ferrous sulphide, which are normally totally miscible. Silicon is readily soluble in molten iron, but sparingly soluble in molten ferrous sulphide. W. P. Jorissen and B. L. Ongkie-hong studied the limits of the reaction between iron and sulphur, and the effect of silica on the results. R. Loebe and E. Becker found that the ferrous sulphide has no influence on the transformation points of iron. A polymorphic transformation of ferrous sulphide occurs at 298° ; and the transformation at 138° was observed with all mixtures containing over 7 per cent. of iron. The brittleness of iron containing sulphide is attributed to this transformation. The eutectic tends to become segregated in mixtures rich in sulphide. Alloys which have been in contact with oxygen contain a new eutectic. Fusion of iron sulphide with iron oxide, however, leads to the elimination of sulphur and formation of ferrite, and the structure is better developed by fusing the sulphide in contact with air.

FIGS. 604 and 605.—Freezing-point Curves of the System : Fe-FeS.

The composition of the eutectic is uncertain. The brittleness of iron containing sulphur at a red-heat is due to the absorption of oxygen in this form. The effect of sulphur on cast iron has been previously considered; F. Wüst and R. Pütz found that the presence of sulphur lowers the solubility of carbon in iron; and E. Piwowarsky and F. Schumacher showed that the effect of sulphur is greater the lower are the carbon and silicon contents of the iron. The subject was investigated by K. Schönrock. D. M. Levy, and T. Liesching studied the ternary system : Fe-S-C, and the former found a ternary eutectic with 2.4 to 4 per cent. of carbon, and 0 to 1.4 per cent. of sulphur. T. Liesching found that the eutectic between iron and carbon is lowered 40° for each per cent. of sulphur.

A. Lacroix⁴ observed pyrrhotite amongst the substances produced during the eruption of Vesuvius in April, 1906; and troilite, found in meteorites, as previously indicated, frequently approximates in composition to that of **ferrous sulphide**, FeS. P. Tschirwinsky found that the troilite in 81 strong meteorites averaged 5.56 per cent. As shown by E. T. Allen and co-workers, E. Manasse, etc., pyrrhotite also occurs in meteorites. Many occurrences of pyrrhotite also approach ferrous sulphide in composition.

Pyrrhotite is not uncommon, though it is only a minor constituent of igneous rocks, and a similar remark applies to pyrite, but pyrrhotite is more characteristic of the ferromagnesian rocks like gabbro, diabase, diorite, norite, augite, and basalt. It often occurs mixed with other pyrites, and, according to A. A. Julien,⁵ occurs in clay slates, mica slates, and in rocks of incipient metamorphism—*e.g.*, in beds of

limestone that have escaped conversion into marble prevailing in adjacent districts. J. H. L. Vogt regarded some pyrrhotite deposits of Norway as direct segregations from silicate magmas. R. Brauns described pseudomorphs of pyrrhotite after pyrite in the shales of Finkenberg, showing that the former was produced from the latter; similar results were observed by W. Eitel, in the basalts of Kassel; O. Mügge, in the shales of Weitisberga; G. Frebold, in the gabbro of Radau, Harz; P. J. Shenon, in sphalerite; C. L. Sagui and A. Jourdan, in the Bottino mine (Florence); and by E. Wildschrey, in the basalts of the Siebengebirges. H. Schneiderhöhn, and F. Wernicke discussed the paragenesis of pyrrhotite, pyrite, and marcasite. E. Harbort attributed the pyrrhotite in the salts of Aller-Nordstern to the formation of iron sulphate by the action of the carnallite on the iron chloride in the salts, and the subsequent reduction of the sulphate to pyrrhotite by the bituminous matters there present. The reduction of iron sulphate to sulphide by organic matter in natural waters was discussed by J. J. Berzelius, and M. E. Chevreul. C. Wurm observed iron intimately associated with the pyrrhotite.

The formation and preparation of ferrous sulphide and pyrrhotite.—Pyrrhotite has been occasionally reported as a furnace product; thus, J. F. L. Hausmann,⁶ and C. W. C. Fuchs found it in prismatic crystals in a Harz furnace; L. Bucca, in a Catania furnace; J. H. L. Vogt, in blast-furnace slags; F. Cornu, in a cinder-heap at Bilin; C. W. Carstens, in a copper matte; C. Reidemeister, in cast-iron retorts used in purifying sulphur; and J. Michael, in preparing alkali bromide from iron bromide and alkali sulphide. M. E. Chevreul found some sulphide *sous le pavé des villes*.

The affinity of sulphur for iron was discussed by C. Frick,⁷ and O. Ruff and B. Hirsch; and G. Tammann and K. Schaarwächter found that when an excess of iron mixed with sulphur is heated, there is a marked evolution of heat at 210°, and the temp. then rises rapidly to about 500°. C. W. Scheele, and N. Sokoloff showed that when a mixture of iron-filings and sulphur is heated, it glows vividly and forms a chemical compound, ferrous sulphide, FeS. According to A. Evain, V. Merz and W. Weith, and J. G. Gahn, when a stick of sulphur is pressed against a plate of red-hot bar iron, not cast iron, the plate is perforated, and iron sulphide is formed; the reaction between the two elements is faster with steel. The reaction was found by F. P. Dunnington to proceed rapidly with raw iron, but A. Evain added that cast iron does not react. W. P. Jorissen and C. Groeneveld said that with a mixture of equal parts of iron and sulphur, the reaction started at one point travels uniformly in different directions; but the reaction is so propagated throughout the mass only with mixtures having between 45.4 and 86.7 per cent. of iron.

J. J. Berzelius, C. Hatchett, L. Gedel, C. F. Rammelsberg, R. Winderlich, G. P. Schweder, and R. Scheuer obtained ferrous sulphide by heating strips of iron with sulphur, not in excess, contained in a crucible, and bending the strips of iron to separate the sulphide. If heat be applied too vigorously, the sulphur fuses with the rest of the iron; and if the sulphur be in excess, pyrite may be formed. The products may approximate FeS in composition, or they may appear as pyrrhotite, that is, as a solid soln. of sulphur in ferrous sulphide. J. L. Proust, C. F. Rammelsberg, and B. G. Bredberg obtained the sulphide by heating in a covered crucible of fireclay or cast iron, a mixture of iron-filings with two-thirds their weight of sulphur; and K. Bornemann, and C. N. Schuette and C. G. Maier melted a mixture of iron with an excess of sulphur in a graphite crucible, under a layer of wood-charcoal, and obtained ferrous sulphide of a high degree of purity. K. Jellinek and J. Zakowsky recommended heating a mixture of sulphur with twice its weight of iron, and afterwards mixing the product with sulphur and heating it in a current of hydrogen. An analogous process was employed by E. Jordis and E. Schweizer, and K. Miyazaki—*vide supra*, Figs. 604 and 605. E. T. Allen and co-workers prepared pyrrhotite by the direct union of iron and sulphur, and added that any excess of sulphur enters into solid soln. with the ferrous sulphide. In meteorites,

the excess of iron renders possible the formation of the monosulphide alone, as troilite. P. Chirvinsky observed that the reactions taking place in the formation of the meteorites are: $6\text{Fe} + 3\text{O} + \text{S} = 6\text{Fe} + \text{SO}_2 + \text{O} = 2\text{Fe} + 3\text{FeO} + \text{FeS}$. Oxidation of iron by oxygen occurs only after complete oxidation of silicon and manganese has taken place, whilst sulphur shows a relatively greater affinity for iron, forming troilite, which on account of its lower f.p. fills the veins and cracks. The black veins in the stone meteorites consist of josite, FeO , and troilite, with scorified silicate material and some iron. The ferrous oxide-ferrous sulphide eutectic, m.p. 1060° , may also be formed. The reaction $3\text{Fe} + \text{SO}_2 = \text{FeS} + 2\text{FeO}$ is exothermic, and proceeds from left to right at fairly low temp.

C. F. Rammelsberg observed that at a low temp. iron disulphide is formed, as the temp. rises, ferric sulphide appears, and at a still higher temp., ferrous sulphide. Analogous observations were made by R. Scheuer, and H. N. Warren. According to L. Gedel, if iron mixed with an excess of sulphur be heated to 450° , or 500° , iron disulphide is formed; at 700° , the product has a composition Fe_7S_8 ; and above 700° , FeS . W. Treitschke and G. Tammann said that for ferrous sulphide, the temp. should be raised to 1400° . A. W. Hofmann observed that iron burns with vivid incandescence in the vapour of sulphur, and N. Juschkevitch added that the vapour begins to act on iron at about 700° forming ferrous sulphide mixed with an excess of sulphur; a similar product is obtained by melting a mixture of iron and sulphur at 1220° in a current of hydrogen. These products yield ferrous sulphide when they are heated with sulphur for 2 hrs. in a current of nitrogen at 1220° . W. Spring found that under a press. of 6500 atm., a powdered mixture of eq. proportions of iron and sulphur forms a homogeneous mass of ferrous sulphide which gives off hydrogen sulphide when treated with acids; with an excess of sulphur, polysulphides are similarly produced. K. Brodowsky studied the joint action of heat and press. on a mixture of iron and sulphur. R. Lorenz stated that if ferrous sulphide be heated with ammonium chloride, well-formed, black, shining crystals of ferrous sulphide appear in the upper part of the crucible.

K. Hilgenstock, A. Ledebur, and N. Juschkevitch obtained ferrous sulphide by the action of hydrogen sulphide on iron between 400° and 500° ; J. B. Peel and co-workers recommended 538° ; and F. Gieseler, 700° . J. Jahn, and F. Schmitz studied the speed of the reaction between iron and hydrogen sulphide at temp. between 100° and 414° . R. Lorenz, E. T. Allen and co-workers, W. G. Mixter, L. Moser and E. Neusser, and S. Meunier obtained crystals of troilite by heating iron to redness in a current of hydrogen sulphide; and J. B. Peel and co-workers obtained silver-white, crystalline, non-magnetic ferrous sulphide of sp. gr. 4.630 by the action of hydrogen sulphide on iron at 1000° . Iron sulphide is also formed by the action of other sulphides on iron; thus, E. Priwoznik found this to be the case with ammonium polysulphides; G. P. Schweder, and G. Tammann and H. Bohner, with cuprous sulphide; R. Lorenz, by the electrolysis of a soln. of potassium chloride with an iron anode and a cathode of cupric sulphide; L. E. Martin, with a soln. of strontium or barium sulphide at 40° to 50° . H. G. S. Anderson, with zinc sulphide; and H. von Jüptner, with lead sulphide. A. Cavazzi found that finely-divided iron, reduced in hydrogen, reacts with carbon disulphide at a red-heat forming ferrous sulphide and graphitic carbon. G. A. Shakhoff and co-workers prepared the sulphide by heating iron in sulphur dioxide in the presence of carbon or carbon monoxide. O. Loew heated iron-filings, water, and carbon disulphide in a sealed tube at 100° , and obtained ferrous sulphide and iron formate. The reaction was discussed by K. Hilgenstock. S. Hilpert and E. Colver-Glauert, K. Hilgenstock, and A. Ledebur observed that sulphur dioxide acts on heated iron forming ferrous sulphide, sulphite, and thiosulphate. A. de Hemptinne found that 62 per cent. sulphuric acid is reduced by iron forming ferrous sulphide. F. Projahn, and L. Hackspill and R. Grandadam observed that at about 1000° , alkali sulphates form ferrous sulphide and ferric oxide; R. Finkener, and K. Hilgenstock, that calcium sulphate forms calcium sulphide and oxide; and

N. W. Fischer, that a mixture of equal parts of iron-filings and charcoal, with twice its weight of lead sulphate, forms lead, and ferrous sulphide. J. Tscherniak and H. Günzburg observed that a mixture of iron, potassium thiocyanate, lime, and carbon also furnishes ferrous sulphide.

K. Brückner, E. Mandowsky, J. L. Proust, C. F. Rammelsberg, R. Scheuer, O. Schumann, T. Sidot, and N. Sokoloff observed that when a mixture of ferric oxide and sulphur is heated, some pyrrhotite or ferrous sulphide and sulphur dioxide are formed; H. Rose passed hydrogen over the heated mixture and obtained analogous results. R. Winderlich employed an excess of sulphur and obtained *reines Eisensulfid*. If hydrogen sulphide alone or mixed with hydrogen chloride be passed over ferric hydroxide, L. Gedel observed that ferrous sulphide and sulphur—as well as some iron disulphide—are formed. L. A. Sayce also noted that ferrous sulphide is formed by the action of hydrogen sulphide on hydrated ferric oxide below 100° —*vide supra*, ferric oxide. A. Gautier, and L. A. Sayce observed that at a red-heat, or, according to M. Picon at 900° , the reaction can be symbolized: $2\text{Fe}_2\text{O}_3 + 7\text{H}_2\text{S} = 4\text{FeS} + 3\text{SO}_2 + 7\text{H}_2$. L. Moser and E. Neusser obtained crystals of the sulphide by heating iron or its oxide in a current of hydrogen and hydrogen sulphide in the proportion 5:1. K. Hilgenstock, and A. Ledebur studied the influence of temp. on the reaction. J. Dewar and H. O. Jones, and K. Hilgenstock obtained ferrous sulphide by the action of carbon disulphide on ferric oxide at a red-heat; O. W. Gibbs, by heating to redness a mixture of ferric oxide and sodium thiosulphate; and J. Tscherniak, by the action of thiocyanates on ferric oxide. Ferrosic oxide behaves similarly; thus, H. Rose passed hydrogen over a red-hot mixture of ferrosic oxide and sulphur, and obtained ferrous sulphide; and C. Fontana showed that the product at a white-heat approximates Fe_3S_4 , the sulphur analogue of magnetite, Fe_3O_4 . The X-radiograms indicate that the Fe_3S_4 is really a solid soln. of ferrous sulphide and sulphur. T. Sidot and C. Friedel, C. Fontana, A. Gautier, and R. Scheuer observed that ferrous sulphide is formed, in yellow, hexagonal crystals when hydrogen sulphide is passed over red-hot ferrosic oxide: $\text{Fe}_3\text{O}_4 + 4\text{H}_2\text{S} = 3\text{FeS} + \text{S} + 4\text{H}_2\text{O}$.

H. Rose, C. F. Plattner, C. F. Rammelsberg, and F. von Schaffgotsch found that all the higher sulphides of iron furnish the monosulphide when heated in hydrogen. K. Friedrich, L. Gedel, G. Ripp, and H. Scheuer also obtained pyrrhotite by heating pyrite; and H. Rose, by heating the pyrite in an atm. of hydrogen. G. Marchal, and B. G. Bredberg observed that when pyrite is melted, it forms ferrous sulphide, or, according to C. F. Rammelsberg, pyrrhotite. The results depend on the duration of the heating; and, according to G. Marchal, and K. Friedrich, with longer periods of heating the product approximates more and more closely to ferrous sulphide. E. Kothny added that at 700° with sulphur vapour at one atm. press. the product becomes very nearly ideal ferrous sulphide. E. T. Allen and co-workers emphasized the difficulty in preparing ferrous sulphide of a high degree of purity; and R. Loebe and E. Becker found that ordinary ferrous sulphide always contains free iron, and some oxide; they obtained a product with 98.72 per cent. FeS by repeatedly melting natural pyrites. F. Foreman was unable to prepare satisfactory pyrrhotite. E. T. Allen and co-workers obtained pyrrhotite by the dissociation of pyrite in an atm. of hydrogen sulphide at 550° ; at 575° , the reverse change occurs, and pyrite is re-formed. E. T. Allen observed that in an atm. of sulphur, pyrite begins to pass into pyrrhotite and sulphur at 575° , the reaction is rapid at 665° , and at 750° , the vap. press. is 1 atm., and decomposition is complete. W. F. de Jong and H. W. V. Willems added that the evolution of sulphur from pyrite is marked at 525° to 550° in vacuo. Ferrous sulphide is formed when pyrite is reduced by hydrogen as shown by A. Andziol, F. Martin and O. Fuchs, H. Rose, G. Gallo, and L. Wöhler and co-workers; by steam at 300° to 400° —L. Benedek; by carbon—J. L. Proust; by aluminium as in the thermite process: $2\text{FeS}_2 + 2\text{Al} = \text{Fe} + \text{Al}_2\text{S}_3$. FeS—N. Parravano and P. Agostini, H. Ditz, and H. Heinrichs; and by iron—N. G. Petinot. L. Michel

heated titaniferous iron intimately mixed with pyrites in a graphite crucible for several hours, and obtained slightly magnetic pyrrhotite, approximating Fe_3S_9 , of sp. gr. 4.5, and hardness 4.

According to F. Stolba, H. Schiff, and E. Glatzel, when anhydrous ferrous or ferric sulphate mixed with sulphur, is heated, ferrous sulphide is formed: $\text{FeSO}_4 + 2\text{S} = \text{FeS} + 2\text{SO}_2$, and, added K. Brückner, some iron disulphide may also be formed. H. Rose obtained similar results by heating a mixture of sulphate and sulphur in a current of hydrogen. According to W. Ipatéeff, anhydrous ferrous sulphate at 330° and 200 atm. press., is reduced by hydrogen to ferrous and ferrosic sulphides, and at 350° and 260 atm. press., to ferrous sulphide alone. P. Berthier found that ferrous or ferric sulphate is reduced by carbon to ferrous sulphide; G. P. Schweder, that the reduction with carbon monoxide yields a mixture of ferrous sulphide, oxide, and metal; and H. Heinrichs and C. A. Becker, that the sulphate is reduced to sulphide by powdered magnesium, aluminium, or iron. H. Arcowsky, J. Durocher, and C. Doelter obtained crystals of troilite by heating ferric chloride in an atmosphere of hydrogen sulphide at 400° . Other sulphides are also formed. C. Doelter heated a mixture of ferrous chloride, sodium carbonate, water, and hydrogen sulphide in a sealed tube for 16 days at 200° , and obtained pyrrhotite when air was excluded, and pyrite when air was present. E. Weinschenk heated a soln. of ferrous chloride with ammonium thiocyanate in a sealed tube at 230° to 250° for 4 hrs., and obtained small, hexagonal plates of ferrous sulphide—J. Milbauer added that some $\text{K}_2\text{Fe}_2\text{S}_4$ is formed at the same time. E. T. Allen and co-workers repeated the experiment and obtained in every case pyrrhotite or ferrous sulphide associated with free sulphur. J. Meyer and H. Bratke obtained crystals of ferrous sulphide by melting a mixture of iron, sulphur, and potassium cyanide in the proportion 1 : 5 : 5; and J. Morel, by heating to redness a mixture of iron filings and antimony sulphide.

A hydrated form of ferrous sulphide is obtained as a bulky, black precipitate when an alkali sulphide is added to a soln. of a ferrous salt: $\text{FeCl}_2 + (\text{NH}_4)_2\text{S} = 2\text{NH}_4\text{Cl} + \text{FeS}$, and if a ferric salt be similarly treated, it is first reduced to ferrous salt and sulphur is simultaneously deposited: $2\text{FeCl}_3 + 3(\text{NH}_4)_2\text{S} = 6\text{NH}_4\text{Cl} + 2\text{FeS} + \text{S}$. The reactions were discussed by H. Baubigny, and F. Fouqué and A. Michel-Lévy. According to W. Feld, when soln. of iron salts are treated with an alkali polysulphide, ferrous sulphide and sulphur are precipitated, and if the soln. be then neutralized, or made feebly acidic, and boiled, iron disulphide is formed. Alkaline substances retard or hasten the transformation, while reducing agents accelerate the change. On the other hand, H. N. Stokes stated that the precipitate which is formed when alkali sulphides are added to soln. of ferric salts is not a mixture of ferrous sulphide and sulphur, but rather ferric sulphide; and that ferric sulphide is the product of the action of alkali polysulphides on soln. of ferrous salts. The precipitation with ammonium polysulphide was studied by G. Buchner, E. Jordis and E. Schweizer, A. B. Macallum, H. Krepelka and W. Podrouzek, W. Mecklenberg and V. Rodt, P. P. Budnikoff and K. E. Krause, and A. Wiener. J. J. Berzelius said that hydrated ferric sulphide is formed if an aq. soln. of a ferric salt be dropped into an excess of an alkali sulphide soln.; but if, on the contrary, the alkali sulphide be dropped into an excess of ferric salt, sulphur is first precipitated, and a ferrous salt is formed, whilst further additions of the alkali sulphide furnish a precipitate of ferrous sulphide. L. Gedel said that if the mixture of ferrous sulphide and sulphur be dried above 100° , some iron disulphide is formed: $3\text{FeS} + \text{S} = \text{FeS}_2 + 2\text{FeS}$. The reaction of hydrogen sulphide, etc., on ferric salt soln. was studied by O. Brunck, L. Gedel, O. W. Gibbs, H. Krepelka and W. Podrouzek, and R. Scheuer. According to L. L. de Koninck, sodium sulphide gives a brown to green coloration with ferrous or ferric salts. The best condition for the green coloration is 320 to 800 mols of sodium sulphide to one gram-atom of iron. The production of the green coloration is retarded by the presence of sodium chloride or sulphate. The subject was studied by G. W. A. Foster.

The action of hydrogen sulphide on soln. of ferrous salts is reversible, $\text{FeSO}_4 \rightleftharpoons \text{H}_2\text{S} + \text{FeS}$; consequently, ferrous sulphide is not precipitated by the action of hydrogen sulphide on acidic soln. The subject was discussed 10. 57, 9. In the language of the ionic theory, the precipitation of ferrous sulphide: $\text{Fe}^{++} + \text{S}'' = \text{FeS}_{\text{solid}}$ is determined by the product $[\text{Fe}^{++}][\text{S}''] = \text{constant}$, which is very small. To ensure the precipitation of all the iron, the concentration of S'' -ions should be proportionally large. Again, in the ionization of hydrogen sulphide, $\text{H}_2\text{S} \rightleftharpoons \text{H} + \text{HS}' \rightleftharpoons 2\text{H} + \text{S}''$, in sat. soln. $[\text{H}]^2[\text{S}''] = K'[\text{H}_2\text{S}]$, where K' is constant. Hence, the greater the concentration of the H^+ -ions, *i.e.* the greater the acidity of the soln., the smaller is that of the S'' -ions. Hence, ferrous sulphide is not precipitated by hydrogen sulphide in acidic soln. The precipitation of ferrous sulphide by hydrogen sulphide is incomplete even in neutral soln., for, as shown by L. L. de Koninck, the supernatant liquor, at the end of the reaction, is green. The presence of sodium acetate in neutral soln. favours the precipitation of ferrous sulphide because the acetate-ions from the sodium acetate unite with the H^+ -ions to form acetic acid, and this reduces the conc. of the H^+ -ions. Hence, as shown by J. L. Gay Lussac, H. Vestner, L. Moser and M. Behr, R. F. Weinland, H. Rose, F. Strohmeier, C. C. Grischo, H. W. F. Wackenroder, and R. Winderlich, ferrous sulphide may be precipitated from soln. containing a weak acid—*e.g.* carbonic, benzoic, oxalic, tartaric, acetic, citric, and succinic acids. H. Dellfs said that no precipitation occurs with formic acid.

The equilibrium constant K of the reaction $\text{FeS} + 2\text{H}^+ \rightleftharpoons \text{Fe}^{++} + \text{H}_2\text{S}$ is $[\text{Fe}^{++}][\text{H}_2\text{S}] = K[\text{H}^+]^2$; and the constant k , or the solubility product for the reaction $\text{FeS} \rightleftharpoons \text{Fe}^{++} + \text{S}''$ is $k = [\text{Fe}^{++}][\text{S}'']$, so that $[\text{Fe}^{++}] = k/[\text{S}'']$. Again, for the reaction $\text{H}_2\text{S} \rightleftharpoons \text{H} + \text{HS}'$, $\text{H}_2\text{S} = [\text{H}][\text{HS}']/k$, where, according to F. Auerbach, and J. Knox, $k_1 = 0.91 \times 10^{-7}$; and for the reaction $\text{HS}' \rightleftharpoons \text{H} + \text{S}''$, $[\text{H}] = k_2[\text{HS}']/[\text{S}'']$, where $k_2 = 1.2 \times 10^{-15}$. Consequently, $K = k/k_1k_2$. L. Bruner and J. Zawadsky found that $k = 3.7 \times 10^{-19}$, so that $K = 3.4 \times 10^3$.

H. Vestner observed that if $N\text{-FeSO}_4$ be sat. with hydrogen sulphide at ordinary temp., and heated under press. at 100° , ferrous sulphide is not precipitated quantitatively, but if ammonium acetate be present, the precipitation is quantitative from soln. with not more than 1.0 gm. of ferrous sulphate per litre; and with neutral 0.001*N*- and 0.0001*N*-soln. of ferrous sulphate, at ordinary press., no precipitation occurs at all. G. Bruni and M. Padoa observed that conc. soln. of ferrous salts, acidified with hydrochloric acid, give a precipitate of ferrous sulphide when treated with hydrogen sulphide at 14.34 to 16.38 atm. press., and at 10° to 15° . From the equilibrium: $\text{FeSO}_4 + \text{H}_2\text{S} \rightleftharpoons \text{FeS} + \text{H}_2\text{SO}_4$, or $\text{Fe}^{++} + \text{H}_2\text{S} \rightleftharpoons 2\text{H}^+ + \text{FeS}$, it follows that the equilibrium constant $K = [\text{Fe}^{++}][\text{H}_2\text{S}]/[\text{H}^+]^2$. By increasing the press., the solubility of hydrogen sulphide in the soln. is augmented, and the conc. of the Fe^{++} -ions in soln. is reduced to maintain the constancy of K . This was proved by M. Padoa and L. Cambi. They found the press. at which ferrous sulphide is precipitated from soln. with a mol of ferrous sulphate per litre, at 22° :

H_2SO_4	—	0.002	0.0025	0.003	0.005	0.001 mol per litre
H_2S (about)	0.3	0.98	2.7	4.0	5.5	9.2 atm.
H_2S	—	0.098	0.27	0.40	0.55	0.92 mol per litre
K	—	10.6×10^3	10.7×10^3	9.7×10^3	3.5×10^3	2.3×10^3

W. Böttger, and R. C. Wells discussed the precipitation of ferrous and copper sulphides from a mixed soln. of copper and ferrous salts; L. Storch studied the joint precipitation of stannous and ferrous sulphides from acid soln. of mixed ferrous and stannous salts; W. Feld, mixed ferrous and zinc salts; E. Schürmann, and F. Feigl, mixed ferrous, zinc, cobalt, and nickel salts; and C. A. O. Rosell, mixed ferric and manganese salts. W. Feld found that ferrous sulphide is quantitatively precipitated by passing hydrogen sulphide into a neutral soln. of a ferrous salt containing an excess of sodium thiosulphate; and the reaction was studied by O. W. Gibbs, and O. Brunck. The precipitation of ferrous sulphide from a soln. of ferrous sulphite by hydrogen sulphide was studied by W. Feld, and

H. W. Hemingway. The anodic separation of sulphide films was studied by E. Beutel and A. Kutzelnigg.

According to S. Veil, ferric oxide prepared by heating iron sulphide obtained by precipitating a ferrous or ferric salt with ammonium sulphide, and afterwards treated with hot water, is more magnetic than the corresponding oxide derived from iron sulphide prepared in the cold. The sulphides show the same difference, the former being most stable to oxidation, and the latter having a magnetization of the same order as that of its corresponding oxide. On redissolving the oxide and reprecipitating the sulphide successively, the magnetizations of both rise to a maximum and then fall.

Black, voluminous **hydrated ferrous sulphide** is precipitated when an alkali sulphide is added to a soln. of a ferrous salt: $\text{FeCl}_2 + (\text{NH}_4)_2\text{S} = \text{FeS} + 2\text{NH}_4\text{Cl}$; and if a ferric salt is used it is first reduced to the ferrous state: $2\text{FeCl}_3 + 3(\text{NH}_4)_2\text{S} = 2\text{FeS} + 6\text{NH}_4\text{Cl} + \text{S}$. As indicated above, ferric sulphide may first be precipitated, and, as indicated below, if an excess of the precipitant is used, sulphoferrites may be formed. The product of the action of moist iron on sulphur—*vide supra*, the action of iron on sulphur—discussed by L. N. Vauquelin⁸—is considered to furnish the hydrated sulphide. The green soln. obtained by the action of iron-filings on water sat. with hydrogen sulphide for 24 hrs., out of contact with air, is supposed by L. N. Vauquelin to be a soln. of hydrated ferrous sulphide; and O. Henry regarded the green soln. obtained by adding calcium sulphide to a soln. of ferrous sulphate as a soln. of the sulphide. The dark green soln. obtained by the action of water on the precipitated hydrate was also considered to show that the compound is soluble in water. More probably it is a case of the peptization of a colloid. J. J. Berzelius found that heat, and the addition of ammonium hydrosulphide or hydrogen sulphide precipitates the sulphide from the green soln. Precipitated ferrous sulphide, like many other hydrogels, may be partially peptized when it is washed, forming a green hydrosol; and J. C. Witt, and A. Berg even noted that the fused sulphide may be partially peptized when it is treated with water. S. M. Kuzmenko found that with mixed soln. of manganese and ferrous sulphates or gelatin, the more soluble sulphide is precipitated first by sodium sulphide.

L. T. Wright prepared a **colloidal solution of ferrous sulphide** by digesting precipitated ferrous sulphide with a soln. of potassium cyanide, and C. Winssinger, by treating ferrous salt with hydrogen sulphide in soln. so dil. that all extraneous compounds can be removed by dialysis before coagulation occurs. L. Sabbatani, J. Hausmann, and S. M. Kuzmenko obtained the colloid by treating a soln. of ferrous sulphate and gelatin with sodium sulphide, but not with ammonium sulphide; J. Lefort and P. Thibault used gum arabic as protective colloid; A. Dumansky and A. Buntin, tartaric acid; H. Rose, organic substances, particularly tartaric acid; A. Müller, glycerol; and L. Sabbatani, cane-sugar. R. E. Stevens obtained it by the action of sodium hydroxide, as peptizing agent, on ferrous sulphide; and C. L. Sagui and A. Jourdan, by the action of sodium sulphide on the metal sulphide. The hydrolysis of the colloid was noted by H. Rose, and A. Kanschegg and H. Malfatti; J. C. Witt found that when the hydrosol is dialyzed through collodion, some sulphur hydrosol, and iron oxide are formed. S. M. Horsch obtained a hydrosol so concentrated that it set to a jelly when cooled to 0°. When air is passed through the green hydrosol, J. C. Witt observed that the green colour changes to brown. P. B. Ganguly and N. R. Dhar observed that the hydrosol is coagulated and oxidized completely by 15 hrs' exposure to tropical sunlight. T. Pinter, and J. Casares studied the colloid. J. H. L. Vogt, and R. Lorenz and W. Eitel observed that ferrous sulphide may form a **pyrosol** in molten silicates. R. F. Weinland found that a soln. of ferric acetate forms a dark green hydrosol when it is treated with ammonium sulphide. N. R. Dhar and A. C. Chatterji observed that the hydrosol is adsorbed by freshly-precipitated ferrous sulphide.

H. Braconnot said that the black mud which collects at the bottom of drains

contains hydrated ferrous sulphide formed by the putrefaction of organic substances in contact with the ferric oxide of the earthy matters. M. Sidorenko called the hydrated ferrous sulphide, $\text{FeS} \cdot n\text{H}_2\text{O}$, which occurs in numerous clays, **hydro-troilite**. According to B. Doss, it is a complex hydroxide. J. Habermann found it in clays; N. Andrussoff, in the mud of the Black Sea; M. Jegunoff, in the mud of the Sea of Azov, and some saline springs; and A. Jentsch, in the mud of the Lake of Plön. The nature of this mineral was discussed by P. Tschirvinsky, and C. L. Sagui and A. Jourdan.

The physical properties of ferrous sulphide and pyrrhotite.—According to L. Gedel,⁹ and R. Scheuer, the colour of powdered ferrous sulphide is greyish-green, and, owing to oxidation, reddish specks of oxide soon appear in the powder. E. Weinschenk, E. T. Allen and co-workers, and R. Lorenz and P. Groth observed that when prepared in a dry way, ferrous sulphide is a brass-yellow crystalline mass which in time darkens and becomes reddish-brown. The colour of pyrrhotite varies from a bronze-yellow to a copper-red, and the lustre is metallic, but the surface soon tarnishes on exposure to air. The streak is greyish-black. E. T. Allen and co-workers found that the colour of synthetic pyrrhotite resembles that of the natural mineral, but when prepared from sulphur and iron, the colour is a little darker than that of the natural mineral. M. Bamberger and R. Grengg observed no change in the colour of the mineral when it is cooled down to -190° ; J. A. Hedvall discussed the colour changes which occur on heating ferrous sulphide.

A. Streng suggested that the **crystals** of pyrrhotite are rhombic and isomorphous with sternbergite, but later concluded that they are hexagonal. The measurements of J. Roth, W. Nicol, K. Vrba, A. Frenzel, and P. A. von Sachsen-Coburg correspond with crystals belonging to the rhombic system; and P. Weiss concluded that the magnetic properties of pyrrhotite indicate that the crystals are probably monoclinic, but do not possess a higher symmetry than rhombic; and E. Kaiser said that the magnetic and other properties show that the mineral occurs in twinned rhombic crystals. J. Morel, and G. Linck thought the crystals were cubic, but this is a mistake. E. Weinschenk reported that the crystals of ferrous sulphide are bronze-yellow, hexagonal plates; and R. Lorenz and P. Groth, and C. Doelter described them as silver-white plates which rapidly tarnish in air. G. Rose measured the axial ratio, and found $a:c=1:0.8701$; E. T. Allen and co-workers gave $1:0.8632$ to 0.8742 ; and P. Groth and K. Mieleitner recalculated G. Rose's data, and gave $1:1.7402$. E. T. Allen and co-workers found that the crystals of troilite and of pyrrhotite are identical. Pyrrhotite usually occurs massive, with a granular structure. Distinct crystals are rare; they are generally tabular, and also acute pyramidal with their faces striated horizontally. C. Doelter observed that the crystals of pyrrhotite prepared in the wet way usually occur in plates, whilst when prepared in the dry way, they furnish columns or needles. L. Bucca obtained isolated crystals, and tabular, iridescent crystals arranged in rosettes. According to J. B. L. Romé de l'Isle, J. F. L. Hausmann, C. C. Leonhard, and J. L. de Bournon, the crystals of pyrrhotite are hexagonal. G. A. Kenngott gave for the axial ratio $a:c=1:1.72315$; W. Nicol, $1:1.419$; and A. Streng, $1:1.165022$. The hexagonal crystals were described by A. d'Achiardi, J. Beckenkamp, L. Bombicci, A. Breithaupt, L. Bucca, K. Busz, E. S. Dana, C. Doelter, H. Ehrenberg, K. Honda and J. Okubo, E. Kaiser, A. Lacroix, H. Miers, O. Mügge, W. Nicol, G. vom Rath, F. Sandberger, G. Seligmann, C. U. Shepard, J. S. Stevenson, G. Hägg and I. Sucksdorff, and A. Streng. Pyrrhotite, however, also occurs in a rhombic form with the axial ratios, according to E. T. Allen and co-workers, ranging from $a:b:c=0.5793:1:0.9267$ to $0.5793:1:0.9927$. H. Heritsch gave $a:b:c=1.170:1:0.778$, and $2V=67^\circ 58'$.

N. Alsén said that the X-radiograms of hexagonal pyrrhotite correspond with a lattice having the parameters $a=3.43$ Å., and $c=5.68$ Å., or $a:c=1:1.66$, with 2FeS mols. in each elementary parallelepiped; concordant data were also reported by W. F. de Jong, P. F. Kerr, W. F. de Jong and H. W. V. Willems,

A. Michel and G. Chaudron, and C. Fontana. N. Alsén observed that a sample of sulphide prepared by adding ammonium sulphide to a soln. of ferrous sulphate, or by the action of moisture on a mixture of iron and sulphur, and then heated half an hour in hydrogen sulphide, had the pyrrhotite structure, and after heating to dull redness, the pyrite structure. Above 200° , A. Michel and G. Chaudron found that pyrrhotite rapidly passes into a ferromagnetic variety with $a=3.47$ Å., and $c=5.72$ Å., and at 450° , this reverts to a metastable variety with $a=3.40$ Å., and $c=5.70$ Å. Precipitated ferrous sulphide behaves similarly, except that above 480° it passes irreversibly into a non-magnetic variety with $a=3.36$ Å., and $c=5.65$ Å.

According to C. Fontana, the interaction of magnetite and hydrogen sulphide, under atm. press. at 1000° , does not furnish Fe_3S_4 , as supposed by T. Sidot and C. Friedel, but rather is the reaction symbolized: $\text{Fe}_2\text{O}_3 \cdot \text{FeO} + 4\text{H}_2\text{S} = 3\text{FeS} + \text{S} + 4\text{H}_2\text{O}$. The sulphur does not occupy a fixed, characteristic position in the crystal-lattice, and the existence of Fe_3S_4 as a chemical individual has not been proved. The lattice constants of troilite are $a=3.43$ Å., $c=5.79$ Å., or $a:c=1:1.686$, while for natural and artificial pyrrhotite they are virtually the same, $a=3.43$ Å., $c=5.68$ Å., or $a:c=1:1.666$. F. Heide and co-workers gave $a=3.439$ Å., and $c=5.855$ Å. for hexagonal troilite. J. W. Gruner pointed out that the S-atoms alone have the positions for hexagonal close-packing; the axial ratio $a:c=1:1.688$ shows that

FIG. 606.—The Space-Lattice Structure of Pyrrhotite.

the packing is not so close as for wurtzite for which $a:c=1:1.633$. The S-atoms form almost regular tetrahedrons which do not contain any metal atoms. Each Fe-atom is surrounded by six S-atoms which are distributed at the corners of a slightly distorted octahedron, Fig. 606. No structural reason for the easy replacement of iron by sulphur atoms has been observed unless it be the tendency for the S-atoms to form S-S-radicles as in pyrite. In pyrrhotite, the replacement of Fe-atoms by S-atoms would bring the S-atoms as close as 2.45 Å., whilst in the pyrrhotite-lattice they are separated by at least 3.43 Å. P. P. Ewald and G. Hermann added that the lattice of hexagonal pyrrhotite belongs to the nicolite type, with six neighbouring atoms at a distance of 2.55 Å. apart. O. Stelling, and V. M. Goldschmidt also discussed the replacement of the atoms of iron in the space-lattice by atoms of sulphur, and inferred that the lattice in consequence is not ionic. The subject was discussed by A. Westgren, G. Hägg and co-workers, and R. Juza and W. Biltz.

W. Orloff said that the crystals of ferrous sulphide are isomorphous with wurtzite, ZnS , greenockite, CdS , and millerite, NiS . A. Breithaupt discussed the isomorphism of pyrrhotite and iridosmine, niccolite, greenockite, millerite, and breithauptite; G. A. Kennigott, with millerite; F. von Kobell, with niccolite; and C. Doelter, with wurtzite. **Twinning** occurs with pyrrhotite about the $(10\bar{1}1)$ -plane with the vertical axes nearly at right angles. The **cleavage** (0001) is sometimes

distinct, and the $(11\bar{2}0)$ -parting less so. A. Streng found that the **corrosion figures** of pyrrhotite with hot hydrochloric acid correspond with hexagonal symmetry. The optical properties of polished surfaces were discussed by J. Murdoch, W. M. Davy, and C. M. Farnham, H. Schneiderhöhn, and B. Granigg. M. Leo, H. C. Boydell, and J. Lemberg discussed the behaviour of polished surfaces with various reagents—nitric, hydrochloric, and sulphuric acids, bromine water, potassium cyanide, potassium hydroxide, and a soln. of copper sulphate, mercuric chloride, and ferric chloride; and J. W. Gruner, and W. H. Newhouse, intergrowths of pyrrhotite crystals. M. J. Buerger studied the deformation of the crystals by pressure.

E. T. Allen and co-workers showed that the crystal constants of pyrrhotite are not invariable because the composition, even of artificial preparations, is not con-

stant. The lack of agreement amongst the crystallographers, indicated above, as to the crystal system of pyrrhotite is explained by the existence of two **allotropic forms**. The ordinary hexagonal form, called β -pyrrhotite, is stable below about 138° ; and the high temp. form, α -pyrrhotite, is stable above that temp., and it furnishes rhombic crystals with the axial ratios indicated above. If hydrogen sulphide is allowed to act on an acidic soln. of ferrous chloride and sulphate at 200° to 225° , tabular, twinned crystals of α -pyrrhotite are formed; and the crystals of β -pyrrhotite are produced when a soln. of ferrous sulphate, sat. with hydrogen sulphide at 0° , is heated in a sealed tube between 80° and 100° for 8 days. The habit of the artificial crystals of the β -variety is hexagonal, and the dominant forms are the prism, and a steep pyramid, whilst the crystals of the α -variety are always tabular, parallel to the base—a few are hexagonal but they are mostly elongated in the direction of the α -axis, and the symmetry is rhombic. The low temp., or β -form, is almost invariably developed as cruciform twins with an angle of about 90° between the two individuals about the twinning $(10\bar{1}1)$ -plane; whilst the high temp. or α -form is usually twinned about the (023) -plane, with the two individuals inclined about 65° to each other; sometimes the twinning is about the (021) -plane; with the two individuals inclined about 55° to each other—*vide supra*.

H. le Chatelier and A. Ziegler noted that the heating curve of ferrous sulphide indicates that there is a **transition temperature** at about 130° ; this was confirmed by W. Treitschke and G. Tammann. R. Loebe and E. Becker, and E. Becker placed it at about 138° . G. Tammann and R. Kohlhaas studied the effect of press. on the transition. F. Rinne and H. E. Boeke observed that two specimens of ferrous sulphide occurring in meteoric iron show the same transition, no break in the cooling curve occurs with a third natural specimen or with a sulphide prepared by heating the elements together without access of air. When the sulphide last mentioned has been fused previously with excess of iron, however, it showed the transition point. When 7 per cent. of iron or more was present, the change took place sharply at 137° , but with less iron it was not so sharp and occurred at lower temperatures; with less than 4 per cent. the break in the cooling curve could no longer be detected. It is, therefore, considered that iron and the sulphide form mixed crystals at 138° which are sat. at 7 per cent. of iron and are readily transformed into another modification. The way in which iron facilitates the transformation has not been elucidated satisfactorily. The fact that the transformation takes place so sharply in troilite, which does not contain excess of iron, is accounted for by the catalytic action of a small proportion of carbon it contains. K. Friedrich, and E. T. Allen and co-workers confirmed these results, and stated that the failure to observe dissolved iron, must mean that the heat absorption in them is so very gradual that its effect is not shown on the heating curve. R. Loebe and E. Becker found that there is a critical temp. on the heating and cooling curve at 298° ; P. Chevenard, one on the thermal expansion curve at 320° ; and H. le Chatelier and A. Ziegler, one on the thermal and expansion curves at 298° . The subject was discussed by R. Lorenz and W. Herz.

L. Playfair and J. P. Joule ¹⁰ gave 5.035 for the mean **specific gravity** of artificial ferrous sulphide; C. F. Rammelsberg gave 4.79 for a sample derived from iron and sulphur, and 4.694 for a sample reduced from pyrite in hydrogen; G. Rose, 4.726 at 9.8° for a sample reduced from pyrite in hydrogen; and E. T. Allen and co-workers, 4.739 at $25^\circ/4^\circ$ for a sample derived from iron and sulphur at 950° , and 4.748 at $25^\circ/4^\circ$ for a sample prepared at 950° using more sulphur. N. Alsén calculated 5.02 for the sp. gr. from the lattice constants, and W. F. de Jong and H. W. V. Willems, 5.01. G. Luck gave 4.52 for the sp. gr. of troilite; C. F. Rammelsberg, 4.817 for a sample with 1.55 to 1.95 per cent. of nickel, 4.75 for a sample with 0.32 per cent. of nickel, and 4.787 for a sample with no nickel; W. J. Taylor gave 4.822 for a sample with 7.26 per cent. of nickel and cobalt; E. Cohen, 4.7379 at 22° for a sample with 4.30 and 1.50 per cent. of nickel and cobalt respectively;

J. L. Smith, 4.75; F. E. Geinitz, 3.98; and S. Meunier, 4.780 to 4.799. The sp. gr. of pyrrhotite was reported by C. F. Rammelsberg to be 4.640; G. A. Kenn-gott gave 4.584; A. d'Achiardi, 4.53; A. Hilger, 4.12 to 4.20; T. Petersen, 4.583; F. von Schaffgotsch, 4.546; J. Thiel, 4.508; G. Lindström, 4.627 to 4.642; G. Nyiredy, 4.5; M. Tournaire, 4.27; J. J. Berzelius, 4.674; C. F. Plattner, 4.627; H. Heritsch, 4.63; P. Berthier, 4.80; and B. J. Harrington, 4.622. Observations were also made by C. Hatchett, H. Habermehl, A. Frenzel, A. A. Julien, M. Palfy, P. Weiss, E. Manasse, A. Serra, W. J. Sharwood, and F. Stutzer and co-workers. C. F. Rammelsberg gave for artificial pyrrhotite (36 per cent. of sulphur), 4.494; C. Doelter, 4.521 for $\text{Fe}_{11}\text{S}_{12}$; L. Bucca, 4.545 for Fe_4S_5 ; L. Michel, 4.5; E. J. L. Holman, 5.02; and J. B. Peel and co-workers obtained 4.63 for the sp. gr. of the synthetic compound FeS ; F. Gieseler, 4.807 at $25^\circ/4^\circ$; and W. Biltz, 4.816. W. F. de Jong and H. W. V. Willems calculated 5.01 for the sp. gr. from the X-radiograms. E. T. Allen and co-workers gave for a series of synthetic pyrrhotites, with different proportions of FeS , and of dissolved sulphur, the following values for the sp. gr. at $25^\circ/4^\circ$, the calculated sp. gr. at 4° , and the calculated specific volume :

FeS . . .	99.59	98.04	96.89	96.57	96.26	95.86	95.23	93.95 per cent.
Excess . . .	0.41	1.96	3.11	3.43	3.74	4.14	4.77	6.04 . . .
Sp. gr. . . .	4.769	4.691	4.657	4.648	4.633	4.602	4.958	4.533
Sp. gr. (calc.).	4.755	4.677	4.643	4.634	4.619	4.589	4.585	4.520
Sp. vol.. . .	0.2103	0.2138	0.2154	0.2158	0.2165	0.2179	0.2181	0.2212

The locus of the sp. vol. is continuous and a straight line in accord with the hypothesis that the excess sulphur is in solid soln., Fig. 607. The dotted line shows the calculated sp. vol. of the sulphur and ferrous sulphide. There is therefore a large contraction in the process of solution. F. Gieseler gave 18.3 for the mol. vol., and calculated 11.2 for the mol. vol. of the contained sulphur, and 28 per cent. contraction during the formation of the sulphide. W. Biltz, and I. I. Saslawsky also discussed the contraction which occurs in the formation of ferrous sulphide and of pyrrhotite.

FIG. 607.—The Specific Volumes of Artificial Pyrrhotites.

The **hardness** of pyrrhotite is between 3.0 and 4.5; and the hardness of troilite is about 4. B. G. Bredberg observed that recently-melted ferrous sulphide is brittle, but is less hard than pyrite; it forms a voluminous powder after a short exposure to air. M. J. Buerger, and F. F. Osborne and F. D. Adams studied the **plastic-deformation** of pyrrhotite. E. J. L. Holman gave 494.4 dynes per sq. cm. for the **surface tension** of ferrous sulphide at about 1176° . J. O. Arnold, and H. le Chatelier and A. Ziegler found that ferrous sulphide diffuses in soft steel between 1000° and 1100° ; and the **diffusion** was discussed by E. D. Campbell—*vide supra*, action of sulphur on iron.

H. Fizeau¹¹ found that the coeff. of **thermal expansion** of pyrrhotite at 40° is $\alpha=0.00000235$ in the direction of the principal axis, and $\alpha=0.00003120$ when perpendicular to that axis. H. le Chatelier and A. Ziegler observed that the relative coeff. of linear expansion α at a temp. θ° when the original length at 100° is taken as zero, is :

	120°	190°	240°	265°	400°	650°
α	0.09	0.00	-0.06	0.00	0.35	0.85

There is thus an irregularity between 100° and 200° which is connected with the change in the crystalline form as β -pyrrhotite passes into α -pyrrhotite. This was discussed by W. Treitschke and G. Tammann. The change between 295° and 300° observed by H. le Chatelier and A. Ziegler, was studied by E. Becker, and R. Loebe and E. Becker. According to P. Chévenard, the thermal expansion of pyrrhotite at 320° is discontinuous, and on cooling, there is an increase in the length of the

sample. On re-heating, the transformation appears at the same temp., but on cooling, the expansion is less. The temp. 320° is therefore considered to represent an enantiomorphic transformation. This temp. also corresponds with a change in the magnetization of the compound. C. H. Lees found the **thermal conductivity** of ferrous sulphide to be 0.017 cal. per cm. per degree per second at 15° . According to A. Streng, and M. Leo, the thermal conductivity of pyrrhotite shows the circular basis characteristic of the hexagonal system; and E. Jannetaz found that the sq. root of the ratio of the conductivities parallel and perpendicular to the principal axis is 1.07.

H. V. Regnault found the mean **specific heat**, c , of artificial ferrous sulphide at 16.57° to be $c=0.1357$; A. de la Rive and F. Marcet gave $c=0.1396$ between 5° and 15° ; and A. Sella, 0.1370. K. Bornemann and O. Hengstenberg found the value of c between 0° and θ° to be:

	100°	300°	400°	500°	600°	700°
c	0.1664	0.2027	0.1888	0.1850	0.1820	0.1813
	800°	900°	1000°	1100°	1200°	
c	0.1760	0.1757	0.1760	0.1773	0.2216	

The results, plotted in Fig. 608, show that there is an irregularity in the result at about 300° , and the transformation is not wholly reversible. The anomaly diminishes with a rise of temp. C. T. Anderson obtained a continuous curve for the mol. ht., C_p , below 25° :

	-215.1°	-198.5°	-153.1°	-84.8°	-51.8°	-28.4°	2.8°	23°
C_p	3.729	5.118	8.395	11.07	11.78	12.07	12.79	13.12

A. Sella, K. Jellinek and J. Zakowsky, and J. Maydell discussed the application of the addition rule—1. 13, 13—to the **molecular heat**. F. E. Neumann gave 0.1533 for the sp. ht. of pyrrhotite; H. V. Regnault, 0.16021 between 9.53° and 99° ; A. Abt, 0.15388 at 13.40° for a specimen with 57.68, Fe; 37.66, S; and 4.42, SiO_2 ; and K. Bornemann and O. Hengstenberg, 0.1547 between 0° and 100° for a specimen with 57.30, Fe; 37.7, S; and 4.75, SiO_2 ; and 0.1531 for "pure" pyrrhotite. K. Bornemann and O. Hengstenberg found that between 0° and 100° the sp. ht. decreased with increasing percentages of sulphur, but not proportionally:

Sulphur	38.0	39.6	40.0	42.5	45.0	47.5	50.0 per cent.
Sp. ht.	0.160	0.152	0.151	0.143	0.137	0.132	0.130

W. A. Tilden gave 0.1459 for the sp. ht. of Fe_3S_4 between 0° and 100° , and 0.1701 between 0° and 300° . G. Linder observed that the mean sp. ht. between 0° and θ° increases markedly with a rise of temp., being 0.1459 at 100° ; 0.1558 at 200° ; 0.1701 at 300° ; and 0.1831 at 350° .

K. Bornemann gave 1194° for the **melting-point** of ferrous sulphide; K. Bornemann and F. Schreyer, 1158° ; C. B. Carpenter and C. R. Hayward, 1163° ; E. J. L. Holman, 980° ; K. Friedrich, 1171° ; R. Loebe and E. Becker, and E. Becker, 1193° ; B. Garre, and W. Biltz, 1197° ; G. Röhl, 1188° ; L. V. Steck and co-workers, 1174° ; D. M. Levy, 1187° ; P. P. Fedotéeff, 1177° ; Z. Shibata, 1163° ; E. T. Allen and co-workers, 1170° in vacuo; and A. C. Halferdahl, 1171° . Very low values were obtained by H. Freeman, H. Weidmann, and H. le Chatelier and A. Ziegler; and the high value, 1300° , of W. Treitschke and G. Tammann shows that the sample was impure. E. T. Allen and co-workers observed that sulphur is slowly given off at the m.p. and a product richer in iron, but of a lower m.p., remains; hence, the augmented values in an atm. of hydrogen sulphide, and sulphur. The presence of an excess of sulphur was found by K. Bornemann to raise the m.p. E. T. Allen and co-workers added that pyrrhotite is a solid soln. of

FIG. 608.—The Specific Heat of Ferrous Sulphide.

sulphur in ferrous sulphide, and the m.p. is raised to 1187° in an atm. of sulphur vapour; and in an atm. of hydrogen sulphide, at 1183° . These temp. correspond with the m.p. of sat. soln. of sulphur in ferrous sulphide. Observations on the subject were made by K. Friedrich. J. H. L. Vogt found that 12.0 grms. of lead sulphide per 100 grms. of ferrous sulphide lowered the m.p. 31° ; and 12.4 grms. of silver sulphide lowered it 38° . F. Thomas, and H. Freeman examined the effect of sodium sulphide on the m.p.; and K. Bornemann, the effect of lead, nickel, and cuprous sulphides.

R. Lorenz observed no evidence of sublimation when ferrous sulphide is heated to whiteness for a long period of time. K. Jellinek and J. Zakowsky calculated from the equilibrium: $\text{FeS} + \text{H}_2 \rightleftharpoons \text{Fe} + \text{H}_2\text{S}$, that the vapour pressure, p , at 730° , 910° , and 1100° is respectively $\log p = -9.15$, -7.09 , and -4.51 ; and N. Paravano and P. de Cesaris calculated from the relation $\log p = -Q/4.561T + 1.75 \log T + 3$, the values 0.079 atm., at 800° ; 0.58 atm. at 900° ; 3.2 atm. at 1000° ; and 13.8 atm. at 1100° . K. Bornemann added that the dissociation pressure at the m.p. is perceptible, but much less than an atmosphere; whilst W. Treitschke and G. Tammann obtained a press. approximating one atm. at the m.p. H. le Chatelier and A. Ziegler, R. Juza and co-workers, and M. Picon also discussed the subject. P. Berthier said that when ferrous sulphide is heated white-hot, out of contact with air it loses no sulphur, and when heated similarly in a carbon crucible, it loses weight

FIG. 609.—The Solubility of Sulphur in Ferrous Sulphide.

very slowly; but J. J. Berzelius observed that sulphur is evolved when ferrous sulphide is heated, and, as indicated above, E. T. Allen and co-workers, as well as W. Treitschke and G. Tammann, and K. Bornemann, found that sulphur is slowly lost at the m.p. R. Kremann and O. Bankovac observed that at 1500° molten ferrous sulphide is a mobile liquid, and bubbly. E. V. Britzke and A. F. Kapustinsky gave $\log p_{s_2} = -14,329T^{-1} + 5.80$ for the dissociation press. of ferrous sulphide. M. Picon noted that ferrous sulphide dissociates into its elements at a high temp. in vacuo; the dissociation begins at 1100° , and is complete at about 1600° . If heated in a coke furnace, the resulting iron is carburized, but the carbon exercises no other influence on the dissociation. H. le Chatelier and A. Ziegler, and G. P. Schweder noted the oxidation of the sulphide when it is melted in air. E. T. Allen and co-workers observed that the sulphur dissolved by ferrous sulphide, at atm. press., is:

	600°	800°	1000°	1100°	1165°	1200°	1300°
Dissolved S .	6.04	4.41	3.6	3.3	3.2	2.5	1.96 per cent.

The results are plotted in Fig. 609. When pyrrhotite is cooled in an atm. of nitrogen from:

	1210°	1200°	1000°	900°	800°	700°	600°
Dissolved S .	0.41	0.63	2.70	3.11	3.74	4.14	4.7 per cent.

At 550° , pyrrhotite passes into pyrite when heated in an atm. of hydrogen sulphide, and at 575° , pyrite begins to change into pyrrhotite, while at about 565° , and a press. of about 5 mm. of sulphur vapour, pyrite is in equilibrium with pyrrhotite containing about 6.5 per cent. dissolved sulphur. The reaction is reversible: $\text{FeS}_2 \rightleftharpoons \text{FeS}(\text{S}_n) + (1-n)\text{S}$. Troilite, or ferrous sulphide, is the end-member of the series of solid soln. The heating curve of pyrite shows a strong absorption of heat at about 665° , indicating that the dissociation is suddenly accelerated, and that the escaping sulphur has a vap. press. of about 1 atm. As previously indicated, L. Gedel found that iron heated with an excess of sulphur to 450° or 500° , forms iron disulphide; at 700° , the product has the composition Fe_7S_8 ; and above 700° , FeS. According to G. F. Hüttig and P. Lürmann, the roasting of ferrous sulphide, derived from pyrite, furnishes a curve, Fig. 610, which indicates that

while most of the sulphur is oxidized when the atmosphere contains 16 per cent. of oxygen, and the remainder sulphur dioxide, not quite all the sulphur is expelled even with 100 per cent. of oxygen. This is taken to mean that a solid soln. of sulphur is formed, otherwise, the course of the reaction would correspond with the dotted curve. The dissociation is discussed in more detail in connection with pyrite.

K. Bornemann and O. Hengstenberg found the **heat of fusion** of ferrous sulphide to be 60 cal. per gram. K. Bornemann calculated 31.9 cal. per gram of FeS; and J. H. L. Vogt, 34.4 cal. J. W. Richards also made an estimate based on an empirical formula—1. 13, 20.

W. G. Mixter found the **heat of formation** of amorphous ferrous sulphide from rhombic sulphur to be (Fe,S)=18.8 Cals.; N. Parravano and P. de Cesaris, 23.07 Cals.; R. Müllenhoff, 25.0 Cals.; E. Mannheimer, 22.813 Cals.; C. T. Anderson, 23.07 Cals.; E. V. Britzke and A. F. Kapustinsky, 18.0 Cals.; and J. Thomsen, 23.75 Cals.

K. Jellinek and J. Zakowsky gave (Fe,S)=39.0 Cals., and A. C. Halferdahl, 37,825 cal. for gaseous sulphur; and if referred to the S₂-molecule, 78.0 Cals. E. V. Britzke and A. F. Kapustinsky gave (2Fe,S₂)=65,460 cal. The value calculated from W. Nernst's formula is 80.6 Cals.; and from J. H. van't Hoff's formula, 62.0 Cals. For the precipitated sulphide, J. Thomsen gave (Fe,S,Aq.)=21.77 Cals., and M. Berthelot, 24.0 Cals. J. Thomsen gave for the heat of the reaction (Fe(OH)₂,H₂S,Aq.)=14.7 Cals.; P. A. Favre and J. T. Silbermann, 18.53 Cals.; and M. Berthelot, 14.6 Cals. J. Thomsen gave for the reaction (Fe(NO₃)₂,H₂S,Aq.)=-6.7 Cals. A. C. Halferdahl found the heat of decomposition of pyrite to form a solid soln. of sulphur and ferrous sulphide, is -10 Cals. at 575° to 680°; he calculated the **free energy** of the reaction $\text{FeS} + \text{H}_2 = \text{Fe} + \text{H}_2\text{S}$ to be respectively -21,170, -19,540, and -17,310 cal. at 730°, 910°, and 1100°; the free energy of ferrous sulphide up to the m.p., 1171°, is -31,820+10.49T; and the free energy at 1171° is -16,670 cal. The free energies at 1200°, 1300°, and 1400° are respectively -16,230, -14,320, and -11,850 cal. From the sp. ht. data of K. Bornemann and O. Hengstenberg, A. C. Halferdahl calculated for the reaction $\text{Fe} + \frac{1}{2}\text{S}_2 = \text{FeS}$, $Q = -35,360$ cal. before fusion at 1171°. The change of **entropy** before fusion is -12.9 units, and -9.7 units after fusion, so that the entropy of ferrous sulphide is 44.5 units after fusion at 1171°. C. T. Anderson gave -23,600 cal. for the free energy, and 16.1 for the entropy at 25°. K. K. Kelley studied the entropy. G. Beck studied the free energy of the sulphide. E. V. Britzke and A. F. Kapustinsky calculated the free energy or affinity of iron for S₂, or $F = -4.571 \log K_p$, to be 38,840 cal. at 996° K.; 36,830 cal. at 1073° K.; 34,360 cal. at 1170° K.; and 30,110 cal. at 1267° K. W. Herz calculated values for the entropy and vibration frequency of FeS.

H. Heritsch¹² gave for the **indices of refraction** $\alpha=1.686$, $\beta=1.693$, and $\gamma=1.696$; and $\alpha-\gamma=0.010$. A. de Gramont found the **spark spectrum** of pyrrhotite resembled that of pyrite; whilst W. W. Coblentz observed that the **ultra-red reflecting power** of pyrrhotite is higher than that of molybdenite, and increases from about 15 per cent. at 1.25 μ to 48 per cent. at 14 μ . O. Stelling S. Tanaka and G. Okuno, O. Lundquist, and F. Butavand discussed the absorption coeff. for the **X-rays**; and C. Doelter found thin layers of pyrrhotite to be transparent to the X-rays, but not so with thick layers. H. E. J. G. du Bois observed no evidence of the **Kerr effect** with ferrous sulphide; and P. Martin obtained with pyrrhotite, Fe₇S₈, a positive rotation approximating 1' with wavelengths between $\lambda=435$ and $\lambda=675$. O. Rohde, and B. Aulenkamp observed that ferrous sulphide exhibits a small **photoelectric effect**, and that the effect with

FIG. 610.—Equilibrium in the System: Fe-S-O₂.

pyrrhotite comes between that with ferrous sulphide and that with pyrite. Observations were also made by W. Ramsay and J. F. Spencer, and B. Aulenkamp. According to E. T. Wherry, pyrrhotite and troilite are only moderate **radio-detectors**.

W. A. D. Rudge¹³ observed that powdered ferrous sulphide in a current of air acquires a positive frictional charge. According to F. Streintz, a rod of compressed powder of ferrous sulphide has a poor **electrical conductivity**; and P. Fischer observed no conductivity at all at 130°. The electrical conductivity of pyrrhotite was measured by M. Faraday, and J. F. L. Hausmann and F. C. Henrici; H. Löwy gave 2×10^{14} c.g.s. units. F. Beijerinck, and R. C. Harvey observed that troilite is a poor conductor, and pyrrhotite a good one, but E. Cohen said that the one conducts as well as the other. J. Guichant, and H. le Chatelier and A. Ziegler observed that artificial ferrous sulphide in the cold is a good conductor. The latter observed that the **electrical resistance** increases five-fold as the temp. rises to 150°; and after that no change occurs until 300° is attained. J. Guinchant observed a decrease in the resistance, R ohms, as the temp. rises to 550°, beyond which there is an increase:

	13°	90°	130°	280°	580°	672°	868°
Heating R	0.0998	0.0314	0.00826	0.00125	0.00087	0.00099	0.00171
	868°	670°	580°	249°	130°	95°	8°
Cooling R	0.00171	0.00112	0.00099	0.00090	0.00605	0.0273	0.105

Between 0° and 100°, $R=0.11146(1-0.00798\theta)$. J. C. McLennan and co-workers found the resistance R microhms of ferrous sulphide to be 1915 at 27°; 1740 at 0°; 450 at -88°; 73 at -268.8°; and 70 at -271.1°. For the molten sulphide, K. Bornemann and K. Wagenmann gave 0.000684 for the temp. coeff. of the sp. resistance between the m.p. 1194° and 1500°; or

	1194°	1200°	1250°	1300°	1350°	1400°	1500°
$R \times 10^4$	5.862	5.883	6.083	6.284	6.485	6.685	7.087

M. Leo reported that the electrical conductivity of pyrrhotite is different when taken parallel and perpendicular to the principal axis. A. Abt gave for the sp. resistance of a sample from Also Jara, $R=0.0084$ and 0.0102 ohm at 20°. K. Baedeker found that the sp. resistance at 0°, of α -pyrrhotite parallel to the c -axis, is $R=0.00035$, and vertical to the c -axis, $R=0.00035$ ohm; there is a minimum in the resistance curve at about 280°; and J. Königsberger and co-workers observed a minimum at 160° when taken parallel to the c -axis, and at 200° when taken vertical to that axis. The resistance of a sample of pyrrhotite, approximating FeS, decreases as the temp. rises from -189° to 300°. There is a transition temp. at about 360° corresponding with the change from α - to β -pyrrhotite, as indicated in Fig. 611, and by the data perpendicular to the c -axis;

FIG. 611.—The Electrical Resistance of Pyrrhotite at Different Temperatures.

	-189°	-95°	-25°	19°	71°	155°	277°	310°
$R \times 10^4$	8.02	6.60	4.23	4.10	3.70	3.25	2.56	2.62 ohms

Between 350° and 360° there is the transition point, or the Curie point. The resistance of the magnetic and non-magnetic forms are the same at 360°; at 417°, $R \times 10^4=2.5$ ohms, and at 463°, 2.5 ohms. When taken parallel to the c -axis, the resistance is:

	-188°	-73°	18°	67°	200°	235°	300°	350°
$R \times 10^4$	10.70	6.45	5.35	5.08	4.25	4.05	3.95	3.87 ohms

The transformation here occurs at 350°. In the vicinity of the transformation point, 350°, 400°, and 445°, $R \times 10^4=380$, 380, and 375 respectively. Observations

were also made by F. Streintz and co-workers. F. Streintz and A. Wellik found that the resistance of pyrrhotite, with increasing load, decreases until 2020 grms. when it remains constant with an alternating current; with a direct current, the load is 3000 grms. T. W. Case observed no change in the electrical resistance of pyrrhotite on exposure to light; and P. Fischer studied the conductivity of mixtures of iron sulphide with the sulphides of silver, and of lead. K. Miyazaki found that the electrical resistance of a soln. of ferrous sulphide in iron, at ordinary temp., can be represented by the curve Fig. 612, and that this agrees with the assumption that the solubility of ferrous sulphide in iron at these temp. is very small.

E. V. Britzke and A. F. Kapustinsky¹⁴ gave -0.43 volt for the **electrode potential** of ferrous sulphide. T. J. Seebeck, W. G. Hankel, W. Flight, and A. Abt placed pyrrhotite between iron and antimony in the thermoelectric series. J. Weiss and J. Königsberger found that with a couple of copper and pyrrhotite, the **thermoelectric force** is 0.000023 volt between 20° and 80° , and the current

flows from the copper to the pyrrhotite at the hot junction. A rod of ferrous sulphide cut parallel to the c -axis gives a thermoelectric force of 0.000026 volt. A. M. Iljef observed that with a rod of compressed ferrous sulphide, between copper electrodes, a thermoelectric current flows in the direction of the fall of temp. The subject was discussed by K. Baedeker, and A. Travers and J. Aubert.

W. Skey¹⁵ gave for the **electrochemical series** in sea-water: $-\text{FeS}$, MnS , ZnS , SnS_2 , HgS , Ag_2S , PbS , Cu_2S , FeS_2 , Sb_2S_3^+ . R. C. Wells found the **electrode potential** of pyrrhotite in $N\text{-KCl}$ to be 0.56 volt, and in $N\text{-Na}_2\text{S}$, -0.17 volt, at 25° —*vide infra*, pyrite—and A. Travers and J. Aubert, the electrode potential of cathodic ferrous sulphide against iron in soln. of sodium sulphate, and of potassium dichromate. R. Zuppinger studied the **electromotive force** of cells of the type $\text{FeS} | \text{FeSO}_4(\text{or NaHS}) / \text{Na}_2\text{SO}_4 | \text{FeSO}_4 | \text{Zn}$. A. Lipschitz and R. von Hasslinger observed that purified ferrous sulphide is passive towards dil. acids, and it is active when metallic iron is present. When measured against a normal calomel electrode, in a soln. of ferrous sulphate and sulphuric acid sat. with hydrogen sulphide, active ferrous sulphide has an e.m.f. of -0.03 volt, which is the same as the e.m.f. of iron; in a soln. of ferrous sulphate in sulphuric acid, passive ferrous sulphide has an e.m.f. of $+0.90$ volt which is similar to the e.m.f. of pyrite, 0.89 volt, marcasite, 0.89 volt, and pyrrhotite, 0.71 volt; with the same soln., iron has an e.m.f. of -0.03 volt. G. Tammann found the e.m.f. of a cell with pyrrhotite against $4N\text{-ZnSO}_4$ and zinc is 1.07 volts; against a sat. soln. of lead chloride and lead, 0.53 volt; against $2N\text{-CuSO}_4$ and copper, 0.19 volt; and against a sat. soln. of silver sulphate and silver, 0.03 volt. G. Trümpler found the e.m.f. of a cell with a ferrous sulphide electrode against $2N\text{-Na}_2\text{S}$ sat. with sulphur, and a calomel electrode, at 15° to 18° , to be 0.667 volt; similar results were observed with electrodes of platinum, galena, and cupric sulphide. E. F. Law studied the potential difference between iron and ferrous sulphide. K. Fischbeck found that ferrous sulphide is not reduced when used as cathode in 2 per cent. sulphuric acid at 20° . M. Padoa and B. Zanella observed that in the electrolysis of a soln. of ammonium chloride with an anode of pyrrhotite, the iron passes into soln. in the ferric state. R. C. Wells studied the anodic and cathodic polarization of pyrrhotite in soln. of potassium chloride. E. F. Smith observed that in the **electrolysis** of pyrrhotite in molten potassium hydroxide using an anode of platinum wire, and a nickel crucible as cathode, both the sulphur and iron are oxidized. R. Kremann and O. Bankovac studied the electrolysis of the molten sulphide.

An alternative name for pyrrhotite is magnetic pyrites, in allusion to its **magnetic properties**; but, according to E. Cohen,¹⁶ and L. H. Borgström, troilite

FIG. 612.—The Electrical Resistance of Solutions of Ferrous Sulphide in Iron.

or ferrous sulphide is non-magnetic, and when it appears to have magnetic properties, in meteorites, this is due to the presence of admixed nickeliferous iron. G. Wiedemann observed that precipitated ferrous sulphide has very feeble magnetic properties; and S. Veil found that the sulphide precipitated and washed in the cold is less magnetic than when it has been washed with hot water. M. Faraday observed that at the temp. of solid carbon dioxide, ferrous sulphide has no magnetization. R. J. Haüy, and C. C. Leonhard knew that pyrrhotite may exhibit polar magnetism, and the magnetic properties were observed by A. Frenzel, A. Delesse, C. B. Greiss, R. Juza and W. Biltz, F. Coeterier, A. Liversidge, O. Mügge, G. A. Kennigott, P. A. von Sachsen-Coburg, and T. Sidot; and C. Hatchett, and L. Bucca examined the effect of the sulphur content on the magnetic properties; and H. How noticed that the strength of the magnetization decreases with the proportion of contained nickel. F. Gieseler said that the synthetic sulphide is non-magnetic, but J. B. Peel and co-workers found the product to be magnetic when the ratio Fe : S is below that required for FeS.

E. T. Allen and co-workers showed that both allotropes of pyrrhotite exhibit polar magnetism, and that with α -pyrrhotite, both poles lie along the a -axis; and with β -pyrrhotite, along the c -axis. A. Streng observed that the pyrrhotite of Bodenmais exhibits polar magnetism, with the north pole on the basal surfaces; if the north pole be stroked with the north pole of a magnet, it is reversed. This subject was discussed by P. Weiss and co-workers, A. Abt, R. H. de Waard, M. Ziegler, and W. Steinhaus and E. Gumlich. A. Streng, and G. Meslin observed that sections of pyrrhotite cut perpendicular to the principal axis are paramagnetic; and P. Weiss showed that the mineral is paramagnetic in the direction of the prismatic axis, and ferromagnetic in a plane perpendicular to that axis. P. Weiss and co-workers found that a crystal of pyrrhotite from Morro Velho, Brazil, exhibited zero magnetization when taken vertical to the base, ferromagnetism in the direction of the magnetic plane, and paramagnetism if vertical to that plane; it was inferred that the crystals of pyrrhotite consist of three simple crystals whose magnetic planes differ from the common plane by 120° . The molecular magnets were supposed to be arranged on a plane perpendicular to the trigonal axis. J. Beckenkamp added that if this were so, three or six such molecular magnets would correspond with a solid trigonal symmetry. The theory was discussed by P. Weiss and co-workers, and by K. Honda and J. Okubo. W. Sucksmith sought for a gyromagnetic effect with pyrrhotite, but the effective magnetization being only 5 per cent. that of magnetite, under similar conditions, the effect was not perceptible.

As a rule, the **magnetic susceptibility** of pyrrhotite is smaller than that of magnetite, but A. Abt found a crystal, approximating Fe_7S_8 , which had a higher susceptibility than magnetite. The ratios of the sp. magnetism of hæmatite : pyrrhotite : magnetite are as 1 : 1.423 : 5.294. B. Bavink found the susceptibility of magnetite to be ten times greater than that of pyrrhotite. F. Stutzer and co-workers gave for the vol. susceptibility of pyrrhotite 7018.0×10^{-6} ; and P. Weiss gave 175×10^{-6} mass unit; and for the atomic susceptibility of the iron, 0.0098, a value close to that obtained for other paramagnetic compounds of iron. The susceptibility above 300° does not change with temp. N. R. Crane gave 6.23×10^{-6} mass unit. The subject was studied by A. Michel and G. Chaudron, D. R. Inglis, G. Grenet, J. Kunz, and W. Lenz. A. Streng, A. Abt, and G. Wiedemann measured the coercive force of pyrrhotite; and the remanences with a current of 48, 6.7, and less amperage, flowing through a copper spiral, about a parallelepiped of pyrrhotite, were respectively 0.08741, 0.00900, and 0.00671. A. Abt gave for the magnetic moment, $M = 93.868$ c.g.s. units, and for a weight $w = 77.73$ grms., the sp. magnetism $M/w = 1.21$. S. Wologdine found that pyrrhotite loses its ferromagnetism at about 300° . The subject was studied by F. Coeterier, and H. Ehrenberg. J. Huggett and G. Chaudron observed that when pyrrhotite is heated in air above 250° it exhibits first an increase and then an

irregular decrease in magnetization up to 340° . P. Weiss and co-workers located the **Curie point** at 348° , and later at 318° to 319° . M. Ziegler found that the magnetization curve rises from the temp. of liquid air, exhibits a maximum at -113° , and then decreases parabolically to 320° , when it abruptly ceases. After cooling a crystal which had been heated above the Curie point, M. Ziegler observed a marked decrease in its magnetizability. The effect of temp. was also discussed by K. Honda and J. Okubo, and J. Forrest; the magnetic anisotropy, by F. Bloch and G. Gentile; the gyromagnetic effect, by W. Sucksmith—*vide* the magnetism of iron.

The chemical properties of ferrous sulphide and of pyrrhotite.—In nature, pyrrhotite alters into pyrite, marcasite, and arsenical pyrites. O. Müller¹⁷ described pseudomorphs of copper pyrites; O. Mügge, arsenical pyrites; F. A. Genth, hisingerite; G. H. Smith, brown iron ore or pyrite; F. Schöndorf and R. Schroeder, J. E. Pogue, J. R. Blum, and A. Lacroix, marcasite; P. von Jereméeff, a mixture of marcasite and pyrite; E. Döll, magnetite; and O. Mügge, cuprite—all after pyrrhotite. Pyrrhotite also readily changes on weathering into limonite, goethite, hæmatite, and iron sulphates. This subject was discussed by F. Senft, J. Roth, G. W. Hawes, D. Forbes, H. Hilpert, G. Gilbert, A. A. Julien, etc.

H. Rose¹⁸ observed that ferrous sulphide is not affected by heating it to redness in **hydrogen**; and F. von Schaffgotsch noticed that when ferrous sulphide is formed by heating magnetic pyrites in hydrogen, the product is non-magnetic. Apparently working at a higher temp., G. P. Schweder observed that the sulphide is reduced: $\text{FeS} + \text{H}_2 \rightleftharpoons \text{Fe} + \text{H}_2\text{S}$. K. Jellinek and J. Zakowsky calculated the thermal value of the reduction between 730° and 910° to be -10.24 Cals., and between 910° and 1100° , to be -10.56 Cals. E. V. Britzke and A. F. Kapustinsky found the equilibrium constant K in the system $\text{FeS} + \text{H}_2 \rightleftharpoons \text{H}_2\text{S} + \text{Fe}$, where $K = p_{\text{H}_2\text{S}}/p_{\text{H}_2}$, to be 0.0008 at 723° ; 0.0012 at 800° ; 0.00185 at 897° ; 0.0037 at 994° ; and also $\log K_p = \log p_{-\text{H}_2\text{S}}/p_{-\text{H}_2} p_{\text{S}_2}^{1/2} = (19,200 - 0.94 \log T - 0.00165T + 0.0637T^2 + 1.60)/4.571$. S. Miyamoto found that the sulphide is reduced by hydrogen, in the silent discharge. F. Fischer and H. Tropsch observed that when iron sulphide is treated with hydrogen sulphide in the presence of steam, a small proportion of sulphur combines with the hydrogen without the steam exerting any oxidizing action, but in the absence of steam, no hydrogen sulphide is formed. J. J. Berzelius observed that moist ferrous sulphide readily oxidizes in **air** with the separation of sulphur, and the heat evolved may be great enough for incandescence; hence, added L. Gedel, the moist sulphide is best dried in an atm. of carbon dioxide. P. de Clermont and H. Guiot added that a rise of temp. up to 50° occurs when the moist sulphide is rubbed between the fingers; and E. Jordis and E. Schweizer observed that when triturated in a mortar, the mass becomes incandescent, and if the excess of sulphur be extracted from the precipitate, by benzene, or carbon disulphide, the residue may be pyrophoric. R. Scheuer found that the freshly-prepared sulphide, cooled out of contact with air, is fairly stable in air. The reaction was studied by H. Saito, and B. Neumann and W. Langer. A. Gélis, A. Wagner, H. le Chatelier and A. Ziegler, and E. Pollacci showed that a little sulphuric acid may be formed when the moist sulphide oxidizes in air; and that raising the temp. to 100° favours the production of sulphuric acid. E. T. Allen and J. Johnston observed the formation of some ferrous sulphate when pyrrhotite is triturated in a mortar. S. Veil found that ferrous sulphide, precipitated in the cold, and washed with cold water, is far more susceptible to oxidation than when it has been washed with hot water. W. Gluud and W. Reise found that ferrous sulphide is more slowly oxidized when suspended in water through which air is bubbled than is the case with ferrous oxide; and an increasing alkalinity in the sodium carbonate soln. in which the sulphide is suspended, retards the oxidation; the oxidation is favoured by raising the temp. from 20° to 40° . Ferrous sulphide precipitated from ferric oxide suspensions is more readily oxidized than that made

from ferrous oxide. This may be due to the presence of ferric sulphide. P. B. Ganguly and N. R. Dhar observed that colloidal soln., in air and sunlight, are oxidized to form colloidal sulphur which is coagulated by further exposure to light. J. J. Berzelius observed that when pyrrhotite is gently heated in air, some ferrous sulphate is formed, but at a higher temp., sulphur dioxide is given off and ferric oxide remains. F. Warlimont observed the formation of sulphate at 400°, and F. Schmitz, at 600° to 700°. J. S. C. Wells, H. Vestner, and F. Strohmeier added that if the roasting occurs at about 200°, ferrous oxide is produced, and at a red-heat, ferric oxide. K. Friedrich said that purified ferrous sulphide has a higher decomposition temp. than is the case when more sulphur is present as in the case of pyrrhotite and pyrites. The temp. of decomposition in a current of oxygen is 555°, and in a current of air, 535°, when the grain-size is 0.1 to 0.2 mm. diameter. The ferrous sulphide does not sinter or decrepitate, but pyrrhotite may decrepitate. Pyrrhotite (58.42, Fe; 37.10, S), of grain-size 0.1 to 0.2 mm., develops sulphur dioxide in oxygen at 533°, and in air at 525°; and H. Saito found that pyrrhotite approximating $\text{Fe}_{10}\text{S}_{11}$, and of grain-size 0.074 mm., begins to develop sulphur dioxide at 430°, and at 800°, the transformation to ferric oxide is complete. E. V. Britzke and A. F. Kapustinsky gave for the heat of oxidation or roasting, $2\text{FeS} + 3\frac{1}{2}\text{O}_2 = \text{Fe}_2\text{O}_3 + 2\text{SO}_2 + 294.84$ Cals. V. Rodt observed that when hydrated ferrous sulphide is oxidized by exposure to air, yellow $\text{FeO}(\text{OH})$ and free sulphur are formed, but no FeS_2 . The oxidation was studied by R. C. Wells, B. Neumann and co-workers, C. R. van Hise, V. H. Gottschalk and H. A. Buehler, W. H. Emmons, F. Foreman, and S. H. Emmens—*vide infra*, pyrites.

F. Cornu found that moist pyrrhotite has a feeble acidic reaction. F. Carmichael found that 0.18 to 0.38 per cent. of sulphur and metal is oxidized when powdered pyrrhotite is agitated with water and oxygen for 13 days; similarly, 0.37 per cent. of troilite was oxidized. O. Weigel calculated the solubility of ferrous sulphide in water, from conductivity measurements at 18°, and obtained 70.1×10^{-6} mol per litre, and for pyrrhotite, 53.6×10^{-6} mol per litre; I. M. Kolthoff doubted the accuracy of these data. R. C. Wells obtained a smaller value, namely 1.9×10^{-11} mol per litre. The assumption is made that the sulphide which dissolves is completely hydrolyzed. A. Jouniaux gave 5.35×10^{-8} gram per litre for the solubility; L. Bruner and J. Zawadsky, $10^{-5.9}$; and L. Moser and M. Behr, $10^{-6.52}$; and they also gave for the solubility product 3.7×10^{-19} on the assumption that the equilibrium constant: $[\text{Fe}^{2+}][\text{H}_2\text{S}] = k[\text{H}^+]^2$, is $K = 3.4 \times 10^3$. For the solubility in 0.01N- H_2SO_4 , L. Moser and M. Behr gave 0.0024 mol. per litre. I. M. Kolthoff discussed these results. F. Foreman reported that the solubility, *S*, parts per million, of pyrrhotite, when heated in sealed tubes, is as follows:

SOLVENT	Dissolved	100°	150°	250°	320°
Water	{ Fe	0.00	0.02	0.00	0.33
	{ Fe eq. of H_2S	—	13.1	32.4	62.4
0.1N- NaHCO_3	{ Fe	100° 0.00	210° 0.08	250° 0.03	275° 0.18
	{ Fe eq. of H_2S	—	27.4	20.1	15.1
0.1N- Na_2S	{ Fe	100° 0.00	210° 0.00	250° 0.00	310° 0.00
	{ Fe eq. of H_2S	—	20.1	30.2	32.4

H. V. Regnault, O. Schumann, and P. de Clermont and H. Guiot observed that when ferrous sulphide is boiled with water, some sulphuric acid and hydrogen are formed; and in an exhausted sealed tube at 56°, P. de Clermont and J. Frommel observed that some hydrogen sulphide is produced; and L. Benedek reported that some ferrous oxide is formed as well as ferric oxide. F. Hoppe-Seyler found that if a slurry is shaken in the presence of air and ammonia, some thiosulphate and sulphur are formed as well as hydrated iron oxide, but no nitrite is produced. H. V. Regnault found that when water vapour is passed over red-hot ferrous sul-

phide, hydrogen and hydrogen sulphide are given off, and a black, magnetic mass remains. The steam first forms hydrogen sulphide and ferrous oxide, and the ferrous oxide reacts with steam to form hydrogen and ferrosic oxide. Not all the sulphur is expelled after 3 hrs'. heating in steam. A. Gautier observed that with powdered ferrous sulphide, at approximately 800° , the gas contained 22 to 32 per cent. H_2S by vol., and 76 to 65 per cent. H_2 ; but with a coarser-grained sulphide, the gas contained 98.94 per cent. H_2 by vol., and 1.06 per cent. H_2S . The residue was ferrosic oxide. F. Fischer and H. Tropsch observed that at 450° to 470° the gas contained 97.3 per cent. of hydrogen by vol., and 2.1 per cent. of H_2S . A. Gautier found that above 800° , some hydrogen sulphide is oxidized to sulphuric acid. F. C. Thompson and N. Tilling studied the reaction: $3\text{FeS} + 4\text{H}_2\text{O} = \text{Fe}_3\text{O}_4 + 3\text{H}_2\text{S} + \text{H}_2$. E. Arbeiter, and J. F. Hernandez examined the action of **hydrogen dioxide** on precipitated ferrous sulphide, and found that in acidic soln., ferric sulphate, or the products of the hydrolysis of ferric sulphate are formed.

H. Moissan observed that **fluorine** in the cold does not act on ferrous sulphide, but at a dull red-heat, white ferric fluoride is formed, and the mass becomes white-hot. H. Rose showed that **chlorine** does not decompose ferrous sulphide in the cold, but E. Zielinsky said that the action starts below room temp., and when heated, sulphur monochloride and ferrous chloride are readily formed. According to L. E. Rivot and co-workers, chlorine oxidizes ferrous sulphide in alkaline soln., to form an alkaline ferrate (*q.v.*). J. Lemberg observed that in alkaline soln., **bromine** oxidizes pyrrhotite rapidly to hydrated ferric oxide. E. Filhol and J. Melliès found that **iodine** in contact with precipitated ferrous sulphide at ordinary temp. forms ferrous iodide and sulphur; the reaction is very slow when iodine acts on ferrous sulphide suspended in cold water, but very rapid if the water is boiling. The reaction with the native sulphide is slow at ordinary temp., but in a sealed tube at 200° , it is very rapid. H. Wurtz observed that unlike pyrite, pyrrhotite is slowly attacked by a freshly-prepared soln. of iodine, and the liquid is slowly decolorized. E. Zalinsky found that pyrrhotite is dissolved very slowly by **hydrofluoric acid**. G. Gore found that liquid **hydrogen chloride** does not attack ferrous sulphide. J. J. Ebelmen observed that ferrous sulphide, prepared at a red-heat by the action of hydrogen sulphide on ferric oxide, is scarcely affected by cold **hydrochloric acid**. As a rule, the mineral acids dissolve purified ferrous sulphide without residue, and with the evolution of hydrogen sulphide; in the case of hydrochloric acid, the dissolution of pyrrhotite may be attended by the separation of sulphur, and the soln. may have a yellow colour owing to the presence of traces of ferric hydroxide; and a green soln. may indicate the presence of nickel. The reaction was studied by A. Streng, and E. Arbeiter.

R. Scheuer observed that when ferrous sulphide is heated with **sulphur**, iron disulphide is formed between 175° and 225° ; ferric sulphide between 400° and 450° ; and pyrrhotite, above 600° . The reaction has been previously discussed in connection with the action of heat on ferrous sulphide, *vide* Fig. 608; and similarly also with **hydrogen sulphide**. G. N. Quam found that liquid hydrogen sulphide has no action on ferrous sulphide. L. L. de Koninck found that ferrous sulphide is insoluble in an aq. soln. of hydrogen sulphide, or **ammonium sulphide**, although it is slightly soluble in aq. soln. of **sodium or potassium sulphide**. A. Terrell found that pyrrhotite readily dissolves in a boiling soln. of sodium sulphide. H. Fincke studied the action of ferrous sulphide on fused sodium sulphide—*vide infra*. L. L. de Koninck and M. Ledent found that sodium polysulphide acts on ferrous sulphide forming a green soln. which W. Mecklenburg and V. Rodt said is stable at 0° ; at 8° , it precipitates ferrous sulphide completely. G. W. A. Foster said that with freshly-precipitated ferrous sulphide, a red soln. is formed which later becomes brown. A. Kanschegg and H. Malfatti observed that ferrous sulphide with ammonium sulphide in the presence of ammonium acetate produces a pale green soln.; and that precipitated ferrous sulphide dissolves in ammonium sulphide. H. Rose observed, contrary to the statement of J. F. Persoz, that ferrous sulphide

can be nearly completely precipitated by ammonium sulphide in the presence of sodium pyrophosphate. The Rhenania Verein Chemischer Fabriken showed that dry **sulphur dioxide** begins to act on ferrous sulphide at 600° , and the yield of sulphur in the reaction: $3\text{FeS} + 2\text{SO}_2 = \text{Fe}_3\text{O}_4 + 5\text{S}$, is about 70 per cent.; and at 800° to 900° , L. Wöhler and co-workers obtained a 100 per cent. yield. The thermal value of the reaction is small, for it amounts to about -17 Cals. The reaction is accelerated in the presence of magnesia, or of ferrous oxide. V. M. Goldschmidt said that the reaction between sulphur dioxide and ferrous sulphide begins at 580° . According to J. Milbauer and J. Tucek, the reaction also progresses: $\text{FeS} + 2\text{SO}_2 = \text{FeSO}_4 + \text{S}$, and $4\text{FeSO}_4 + \text{S} = 2\text{Fe}_2\text{O}_3 + 5\text{SO}_2$, and the relative proportions of ferrous sulphate and ferric oxide at different temp., are:

	500°	600°	700°	800°
FeSO_4	22.75	19.84	13.46	—
Fe_2O_3	8.97	39.35	80.79	99.63

E. Diepschlag and E. Horn represented the reaction which occurs at 800° by $3\text{FeS} + 2\text{SO}_2 = \text{Fe}_3\text{O}_4 + 5\text{S}$. A. C. Halferdahl calculated for the free energy of the reaction: $3\text{FeS} + 2\text{SO}_2 = \text{Fe}_3\text{O}_4 + 2\frac{1}{2}\text{S}_2$, 6800 cal. at 600° , and 5800 cal. at 1400° ; and for $2\text{FeS} + \text{SO}_2 = 2\text{FeO} + 1\frac{1}{2}\text{S}_2$, 14,500 cal. at 600° , and 2400 cal. at 1400° . According to A. Guerout, when sulphur dioxide acts on ferrous sulphide suspended in water, some heat is developed, and hydrogen sulphide, sulphur, and thiosulphate are formed. W. E. Henderson and H. B. Weiser represented the reaction $\text{FeS} + \text{H}_2\text{SO}_3 = \text{H}_2\text{S} + \text{FeSO}_3$, and some thiosulphate is also produced. If the slurry of ferrous sulphide be added to conc. **sulphurous acid**, the excess of sulphur dioxide oxidizes the hydrogen sulphide, and prevents the formation of ferrous sulphite; so that the reaction is represented: $2\text{FeS} + 3\text{SO}_2 = 2\text{FeS}_2\text{O}_3 + \text{S}$. F. Förster and J. Janitzky studied the reaction. W. Feld observed the formation of tetrathionate in neutral soln.: $\text{FeS} + 3\text{SO}_2 = \text{FeS}_4\text{O}_6$, and F. Förster and J. Janitzky observed the formation of the following relative proportions: $\text{S}_2\text{O}_3''$, 5.2 millimols; $\text{S}_3\text{O}_6''$, 0.1; $\text{S}_4\text{O}_6''$, 1.8; $\text{S}_5\text{O}_6''$, 0.8; and S, 3.0. L. L. de Koninck noted the solubility of ferrous sulphide in sulphurous acid. H. B. North and C. B. Conover represented the action of **thionyl chloride** in a sealed tube at 150° to 200° , by the equation: $6\text{FeS} + 16\text{SOCl}_2 = 6\text{FeCl}_3 + 8\text{SO}_2 + 7\text{S}_2\text{Cl}_2$. H. Danneel and F. Schlottmann studied the action of **sulphuryl chloride**. L. Moser and M. Behr observed that a litre of 0.1*N*-**sulphuric acid**, sat. with hydrogen sulphide, dissolved 0.2136 grm. FeS, or 2.4×10^{-3} mol, at 20° . The effect of hydrogen sulphide in the soln. under press. has been previously discussed, G. Bruni and M. Padoa suggested that possibly some polysulphide is formed. According to G. S. Nishihara, the attackability of pyrrhotite by 0.125*N*- H_2SO_4 is 100, when that of pyrite is unity; and R. C. Wells obtained a similar result. P. Casamajor found that the dissolution of ferrous sulphide in dil. sulphuric acid is favoured by the presence of zinc. According to A. Lipschitz and R. von Hasslinger, purified ferrous sulphide reacts only extremely slowly with cold, dil. acids. "Active" ferrous sulphide, which evolves hydrogen sulphide with cold dil. acids, contains metallic iron; the hydrogen formed by the action of the acid on the free iron reduces the ferrous sulphide to hydrogen sulphide and iron, so that a small amount of free iron acts as an accelerator of the reaction. A. E. H. Tutton found that **selenic acid** converts ferrous sulphide into ferrous selenate and hydrogen sulphide is evolved; V. Lenher and C. H. Kao, that **selenium monochloride** at 100° , forms ferrous chloride with the liberation of sulphur and selenium; and V. Lenher, that **selenyl bromide** forms ferric bromide and **selenium monobromide**.

E. C. Franklin and C. A. Kraus found ferrous sulphide to be insoluble in liquid **ammonia**. Ferrous sulphide is insoluble in aq. ammonia. P. de Clermont observed that precipitated ferrous sulphide is easily dissolved by soln. of **ammonium salts**; although R. H. Brett said that the ordinary sulphide is insoluble in soln. of ammonium nitrate or chloride; R. Lorenz found that when ferrous sulphide is

heated with ammonium chloride, some ferrous chloride is volatilized. P. de Clermont found that ammonium salts of organic acids—oxalic, tartaric, and succinic—form the corresponding ferrous salts when they act on ferrous sulphide. T. W. B. Welsh and H. J. Broderick showed that 100 grms. of **hydrazine** dissolve 9 grms. of ferrous sulphide with decomposition at room temp. J. J. Berzelius found that **nitric acid** dissolves ferrous sulphide forming nitric oxide; and C. Hatchett, that nitric acid of sp. gr. 1.38 diluted with an equal vol. of water, does not act on pyrrhotite in the cold, but when the acid is heated, the sulphide dissolves. S. Meunier observed that troilite is not attacked by cold, fuming nitric acid. R. F. Weinland and L. Storz found that **sodium arsenite** acts on ferrous sulphide, and pyrrhotite forming ferric oxide and hydrogen sulphide which reacts with the arsenite to form sulphoarsenite; L. Storch found that ferrous sulphide is soluble in soln. of **alkali sulphoarsenates, sulphoantimonates, sulphovanadates, sulphostannates, sulphomolybdates, and sulphotungstates.**

Ferrous sulphide is reduced to the metal when it is heated with **carbon**; and, according to N. Parravano and G. Malquori, the formation of carbon disulphide: $2\text{FeS} + \text{C} = \text{CS}_2 + 2\text{Fe}$, begins at about 1200° . O. Meyer noted that **silicon carbide** is attacked by ferrous sulphide at 1200° . T. Sato, and H. Hanemann and A. Schildkötter studied the action of **iron tritacarbide** in the quasiternary system Fe-FeS- Fe_3C , and found a ternary eutectic at 975° with 10.5 per cent. Fe, 87 per cent. FeS, and 2.5 per cent. Fe_3C . No ternary solid soln. was observed at the Fe_3C corner of the ternary diagram; and only a small range in the iron corner as the solid solubility of sulphur in iron does not exceed about 0.03 per cent. The solubility of iron in ferrous sulphide at the ternary eutectic temp. is about 3 per cent., and that of Fe_3C in iron at the same temp. is 20 per cent. Molten mixtures having a composition indicated by any point on the straight line joining the Fe- Fe_3C eutectic to the Fe-FeS eutectic in the triangular diagram, separate into two liquid phases—the upper one containing 0.22 per cent. C and 30.65 per cent. S, and the lower one, 4.12 per cent. C and 0.98 per cent. S. In Fig. 613, O represents the ternary system with 87 per cent. FeS, 2.5 per cent. Fe_3C , and 10.5 per cent. Fe; E_1 , E_2 , and E_3 represent binary eutectics; DF, the line of separation of the heterogeneous two-phase solid soln. of iron and iron sulphide from the heterogeneous three-phase soln. F represents the conc. of the sat. soln. with 97 per cent. of FeS.

FIG. 613.—The Ternary System: Fe-FeS- Fe_3C .

K. Stammer said that **carbon monoxide** does not act on ferrous sulphide; and A. Foss and B. J. Halvorsen observed that **carbon dioxide** reacts furnishing ferric oxide, carbon monoxide and sulphur dioxide; the reaction begins at 600° , and progresses best at about 1000° when the reacting mass does not fuse. M. Costeanu said that at 1000° , the reaction progresses: $\text{FeS} + \text{CO} = \text{FeO} + \text{CO} + \text{S}$, and at 1100° , $3\text{FeS} + 4\text{CO}_2 = \text{Fe}_3\text{O}_4 + 4\text{CO} + 3\text{S}$. V. M. Goldschmidt found that the reaction: $\text{FeS} + 3\text{CO}_2 = \text{FeO} + 3\text{CO} + \text{SO}_2$ does not occur below 630° , and a temp. of 1150° is necessary for an appreciable reaction. F. von Schaffgotsch observed that no sulphur is dissolved when pyrrhotite is shaken with **carbon disulphide**, although C. Bodewig, and E. Jordis and E. Schweizer said that some sulphur is dissolved. T. Sato studied the system with iron and **iron carbide**. J. Lemberg observed that ferrous sulphide is soluble in a soln. of **potassium cyanide**; and with a boiling soln., L. T. Wright, G. W. A. Foster, and T. G. Pearson and P. L. Robinson observed that some potassium ferrocyanide is formed. W. Wanjukoff observed that only traces of the sulphide are dissolved by a sat. soln. of potassium cyanide, and N. Juschkevitch found the sulphide to be insoluble in a 7 per cent.

soln. G. P. Lewis represented the reaction in the presence of potassium carbonate: $2K_2CO_3 + FeS + 6HCy = K_4FeCy_6 + H_2S + 2CO_2 + 2H_2O$. H. L. Dunlap found that when heated 2 hrs., at 340° , with **paraffin**, a little hydrogen sulphide is evolved, and the residue is magnetic. E. Jordis and E. Schweizer observed that **benzene**, and **alcohol** extract some sulphur from ferrous sulphide when treated for several days in an extraction apparatus. M. Berthelot found that **ether** extracts sulphur from ferrous sulphide, and pyrrhotite. A. Naumann observed that ferrous sulphide is insoluble in **methyl acetate**; and A. Naumann, and M. Hamers, in **ethyl acetate**. F. Stolle showed that 10, 30, and 50 per cent. soln. of **sugar** dissolve respectively 3.8, 7.1, and 9.9 mgrms. of ferrous sulphide per litre at 17.5° ; 3.8, 9.1 and 19.8 mgrms. respectively at 45° ; and 5.3, 7.2, and 9.1 mgrms. respectively at 75° . A. Naumann and J. Schröder found that ferrous sulphide is insoluble in **pyridine**. G. Röhl observed that an alcoholic soln. of **picric acid** colours deep blue on a yellow ground, inclusions of ferrous sulphide in steel which has been quenched from a yellow heat. H. C. Bolton found that pyrrhotite is attacked in the cold by **citric acid**, and some hydrogen sulphide is evolved. J. Spiller said that ferrous sulphide is not completely precipitated in the presence of **sodium citrate**. T. Turner, and K. Hilgenstock observed no reaction between **silicon** or **ferrosilicon** and fused ferrous sulphide. W. P. Jorissen and B. L. Ongkiehong, and J. H. Andrew and W. R. Maddocks examined the effect of **silica** on the reaction between sulphur and iron. W. Jander, and W. Jander and K. Rothschild studied the action of various **metal silicates**—lead, copper, and nickel—on ferrous sulphide; and W. Jander and co-workers, and B. P. Selwanoff and co-workers, of **ferrous silicate**. W. Treitschke and G. Tammann said that **porcelain** is attacked strongly when heated with ferrous sulphide, but K. Friedrich observed that the sulphide alone does not attack porcelain, it does so only when partially oxidized. E. T. Allen and co-workers observed no attack when air is excluded. A. Cayphas studied the action of furnace slags on iron sulphide.

A. Colson observed that a polished piece of ferrous sulphide resting on a **copper** plate, in an atm. of carbon dioxide, gives up some sulphur to the copper. K. Hilgenstock, and A. Ledebur discussed alloys of ferrous sulphide and copper. The reaction was studied by A. Baykoff. B. Garre found that when ferrous sulphide is heated with **magnesium**, a reaction: $FeS + Mg = MgS + Fe$, begins at 470° , which is violent at 670° , and the thermal value is 56.3 Cals. H. Ditz observed that with **aluminium** in the thermite process: $3FeS + 2Al = Al_2S_3 + 3Fe$, about 25 per cent. remains in the slag as $FeS \cdot Al_2S_3$. The reaction was also discussed by G. Tammann and H. Bohner, T. R. Haglund, K. Hilgenstock, F. A. Livermore, A. Ledebur, A. McCance, and N. Parravano and P. Agostini. K. Hilgenstock, and A. Ledebur found that **chromium** acts on molten ferrous sulphide removing some of the sulphur, and forming a slag. H. von Jüptner observed that ferrous sulphide is decomposed when it is heated with **manganese** since the press. of the sulphur is smaller with manganese sulphide than it is with ferrous sulphide. The reaction $FeS + Mn = Fe + MnS$ is exothermal, and it is utilized in the desulphurization of steel—*vide supra*, action of sulphur on **iron**. The reversible reaction was studied by K. Hilgenstock, A. Ledebur, R. Vogel and H. Baur, G. Tammann and H. Bohner, and C. H. Herty and O. S. True. G. P. Schweder observed that molten ferrous sulphide can dissolve some iron; and the solubility of ferrous sulphide in steel was discussed by J. H. Andrew and D. Binnie. P. Berthier observed that when the molten mixture of ferrous sulphide and iron is cooled, two layers are formed, and they are easily separated by a blow from a hammer—*vide supra*, Fig. 604. K. Hilgenstock, A. Ledebur, and J. H. L. Vogt observed that **nickel** acts on molten ferrous sulphide: $FeS + Ni \rightleftharpoons NiS + Fe$; and J. H. L. Vogt said that the reaction is similar with **cobalt**.

A. Konschegg and H. Malfatti found that ferrous sulphide is insoluble in an aq. soln. of **alkali hydroxide**, but if sulphur be present, added purposely, or brought in when the ferrous sulphide has been formed by adding ammonium polysulphide

to a soln. of ferric chloride, a dark green soln. is formed, which, as suggested by L. L. de Koninck, as in many other cases is probably a case of the peptization of the colloid. A. Konschegg and H. Malfatti supposed, however, that the dissolution is due to the formation of a thioferrate. J. D. Clark and P. L. Menaul found that with pyrrhotite ground to pass a lawn of 0.05 mm. mesh, 0.01N-KOH begins to form a colloidal soln. in about 6 days, and in 67 days, 2.22 per cent. of the mineral is in colloidal soln. They also discussed the effect of lime and alumina on the reaction. A. Terreil, and C. F. Becker observed that a brown soln. is frequently produced at first, and this turns green on exposure to air. The reaction was shown by L. L. de Koninck, and A. Villiers to be so very sensitive that if the $\text{FeS} : \text{KOH} = 1 : 4,000,000$ the coloration appears. P. Berthier found that when ferrous sulphide is heated to low redness with about twice its weight of **alkali carbonate**, a black, crystalline, magnetic mass is formed from which water extracts alkali sulphide containing a trace of sulphate; if the mixture is heated to whiteness in a carbon crucible, cast iron is formed. R. Finkener showed that the desulphurization of ferrous sulphide by **calcium oxide** is an important reaction in the blast-furnace; calcium oxide alone does not act on ferrous sulphide; but it does so in the presence of reducing agents—*e.g.*, G. Hilgenstock, and B. Osann found that with hydrogen, the reaction is symbolized: $\text{FeS} + \text{CaO} + \text{H}_2 = \text{CaS} + \text{Fe} + \text{H}_2\text{O}$; A. Ledebur, with carbon: $\text{FeS} + \text{CaO} + \text{C} = \text{CaS} + \text{Fe} + \text{CO}$; and B. Osann, with carbon monoxide: $\text{FeS} + \text{CaO} + \text{CO} = \text{CaS} + \text{Fe} + \text{CO}_2$. G. Tammann and H. O. von Samson-Himmelstjerna observed that the heat of the reaction: $\text{FeS} + \text{RO} = \text{FeO} + \text{RS}$, is 1.9 Cals. with calcium oxide, 11.1 Cals. with **strontium oxide**, 15.6 Cals. with **barium oxide**, and -1.5 Cals. with **zinc oxide**. H. N. Stokes found that precipitated ferrous sulphide does not react with an ammoniacal soln. of **zinc hydroxide** in the cold, or at the b.p., but between 160° and 170°, there is a slow reaction forming colourless ferrous hydroxide and zinc sulphide. T. R. Haglund represented the reaction with **alumina**: $\text{Al}_2\text{O}_3 + 3\text{FeS} + 3\text{C} = \text{Al}_2\text{S}_3 + 3\text{Fe} + 3\text{CO}$. P. Berthier observed that when ferrous sulphide is fused with 30 times its weight of **lead oxide**, sulphur dioxide is evolved, and lead, and a slag containing lead and ferrous oxide are produced; and with 5 times its weight of lead oxide, the mixture swells up when strongly heated to form a grey, homogeneous, magnetic slag containing sulphides of iron and lead. G. Tammann and H. O. von Samson-Himmelstjerna found for the heat of the reaction: $\text{FeS} + \text{PbO} = \text{PbS} + \text{FeO} + 10.6$ Cals., and with **manganese oxide**, -2.8 Cals. B. Osann, and H. Skappel showed that manganese oxide and carbon react on ferrous sulphide: $\text{FeS} + \text{MnO} + \text{C} = \text{Fe} + \text{MnS} + \text{CO}$. J. H. L. Vogt said that **ferrosic oxide** is nearly insoluble in molten ferrous sulphide. F. S. Wartman and G. L. Oldright observed a small reduction of magnetite by ferrous sulphide at 1000°, and the reduction was rapid at higher temp. Orthoclase, albite, anorthite, china-clay, silica, and magnesia accelerate the reaction, whereas the reaction is retarded by lime, alumina, and cuprous sulphide. A. C. Halferdahl calculated for the reaction $4\text{Fe}_3\text{O}_4 + \text{FeS} = 13\text{FeO} + \text{SO}_3$, the free energy 97,300 cals. at 600°, and 35,100 cals. at 1400°; for $3\text{Fe}_3\text{O}_4 + \text{FeS} = 10\text{FeO} + \text{SO}_2$, 52,200 cals. at 600°, and -5300 cals. at 1400°; and for $\text{Fe}_3\text{O}_4 + \text{FeS} = 4\text{FeO} + \frac{1}{2}\text{S}_2$, 22,200 cals. at 600°, and -900 cals. at 1400°. G. Tammann and H. O. von Samson-Himmelstjerna gave: $3\text{FeS} + 2\text{Fe}_2\text{O}_3 = 7\text{Fe} + 3\text{SO}_2 - 48.6$ Cals.; and for $\text{FeS} + 2\text{FeO} = 3\text{Fe} + \text{SO}_2 - 83.0$ Cals. E. D. Campbell obtained what might have been impure **ferric oxysulphide**, Fe_2OS_2 , by melting together a mixture of ferrosic oxide and ferrous sulphide. C. F. Rammelsberg obtained what he regarded as an oxysulphide by the action of hydrogen sulphide on ferric oxide below redness, and F. Martin and O. Fuchs, and L. Wöhler and co-workers represented the reaction at 900° to 1000° by the equation: $\text{FeS} + 3\text{Fe}_3\text{O}_4 = 10\text{FeO} + \text{SO}_2$; and the reaction with **ferric oxide**, which begins at 550° and is completed at 800°, by $\text{FeS} + 10\text{Fe}_2\text{O}_3 = 7\text{Fe}_3\text{O}_4 + \text{SO}_2$ —the ferrosic oxide at a higher temp. reacts as indicated above. P. Tschirwinsky, A. C. Halferdahl, and E. Diepschlag and E. Horn studied the reaction. The reaction with ferric oxide commences at 550° and is complete at 800° to 850°.

Between 850° and 1100° no reaction occurs between ferrosic oxide and ferrous sulphide, but at higher temp. the reaction: $\text{FeS} + 3\text{Fe}_3\text{O}_4 = 10\text{FeO} + \text{SO}_2$ takes place, 77.5 per cent. of the iron being converted into ferrous oxide at 1220°; above 1300°, a small amount of free sulphur is formed and the solid product contains traces of metallic iron. L. T. Wright represented the heat of the reaction with ferric oxide by 86.2 Cals. A. C. Halferdahl calculated for the reaction: $4\text{Fe}_2\text{O}_3 + \text{FeS} = 9\text{FeO} + \text{SO}_3$ the free energy 52,100 cals. at 600°, or 9500 cals. at 1400°; for $4\text{Fe}_2\text{O}_3 + \text{FeS} = 3\text{Fe}_3\text{O}_4 + \frac{1}{2}\text{S}_2$, -8300 cals. at 600°, and -29,700 cals. at 1400°; and for $10\text{Fe}_2\text{O}_3 + \text{FeS} = 7\text{Fe}_3\text{O}_4 + \text{SO}_2$, -24,200 cals. at 600°, and -82,300 cals. at 1400°. P. Tschirwinsky said that the eutectic with ferrous sulphide and **ferrous oxide** (4:1) is at 1060°. A. C. Halferdahl calculated for the reaction: $2\text{FeO} + \text{FeS} = \text{SO}_2 + 3\text{Fe}$, the free energy 53,000 cals. at 600°, and 23,500 cals. at 1400°, but the reaction does not proceed spontaneously. H. le Chatelier and A. Ziegler also studied the subject. G. P. Schweder fused a mixture of **nickel oxide** and ferrous sulphide under borax, and obtained a magnetic, brass-yellow mass containing nickel oxide and sulphide.

G. Buchner found that a boiling soln. of **sodium pyrosulphate** dissolves ferrous sulphide to form a colourless soln., which, when cold, is green. A. Gorgeu found that molten **sodium sulphate** oxidizes ferrous sulphide to ferrosic oxide; and M. Websky found that molten **potassium hydrosulphate** dissolves ferrous sulphide forming a deep brown mass which is pale yellow when cold. F. Raschig, and C. Meinecke observed that a soln. of **cuprous chloride** in the presence of sodium chloride gives with ferrous sulphide a precipitate of cuprous sulphide; and a soln. of **cupric chloride** furnishes ferrous chloride and cupric sulphide. W. F. K. Stock said that a boiling, ammoniacal soln. of cuprous chloride transforms 80 per cent. of ferrous sulphide to chloride. E. F. Anthon, and L. T. Wright also observed that hydrated ferrous sulphide precipitates copper sulphide from soln. of copper salts. E. F. Anthon, L. T. Wright, P. L. Robinson and co-workers, and O. Ruff and B. Hirsch observed that cold, and boiling soln. of **copper sulphate** give a precipitate of copper sulphide; but S. Meunier added that troilite is not attacked. The active and inactive forms of ferrous sulphide observed by A. Lipschitz and R. von Hasslinger, were discussed above. F. F. Grout observed that some varieties of pyrrhotite act slowly on an acidic soln. of copper sulphate, and some varieties do not act at all—and this, added G. S. Nishihara, even at a high temp. E. G. Zies and co-workers reported that natural or artificial pyrrhotite, when heated 3 days with a 5 per cent. soln. of copper sulphate, at 200°, is converted into copper pyrites, CuFeS_2 . C. Palmer and E. S. Bastin found that pyrrhotite reduces soln. of **silver salts**; J. Lemberg observed that a sulphuric acid soln. of silver sulphate becomes brownish-violet or blue when warmed with pyrrhotite. E. F. Anthon, L. T. Wright, and O. Ruff and B. Hirsch also observed that hydrated ferrous sulphide precipitates silver or silver sulphide from soln. of silver nitrate. F. Zambonini, and M. Leo said that the reducing action of ferrous sulphide on soln. of **gold chloride** is stronger than it is with other metal sulphides; the layer of gold produced by pyrrhotite in 24 hrs. is thicker than it is with pyrite in 8 days. R. J. Traill and W. R. McClelland found that pyrrhotite, but not pyrite, dissolves readily in a soln. of **ferric chloride**.

F. Martin and O. Fuchs observed that **calcium sulphate** reacts with ferrous sulphide producing calcium ferrite and sulphur dioxide: $16\text{FeS} + 23\text{CaSO}_4 = 4\text{Ca}_3\text{Fe}_4\text{O}_9 + 11\text{CaS} + 28\text{SO}_2$; and between 920° and 930°, the yield is 8 to 9 per cent. of sulphur dioxide per hour, and at 950°, 13 per cent. A suitable mixture for preparing sulphur dioxide is: $2\text{FeS} + 4\text{CaSO}_4$; with **strontium sulphate**, the most favourable temp. is 1075°; and with **barium sulphate**, 1175° to 1225°. C. Künzel found the reaction with sand in addition, at a red-heat, can be represented: $3\text{BaSO}_4 + 4\text{SiO}_2 + \text{FeS} = 3\text{BaSiO}_3 + \text{FeSiO}_3 + 4\text{SO}_2$. E. Schürmann found that a soln. of **zinc sulphate** is completely precipitated by ferrous sulphide; and O. Ruff and B. Hirsch added that after 60 mins' boiling, the precipitate contains 14.3

gram-atoms of Zn, to 0.40 of Fe. H. N. Stokes found that an ammoniacal soln. of **zinc chloride** has no action on precipitated ferrous sulphide at ordinary temp., but in a sealed tube at 160° to 170°, ferrous hydroxide and zinc sulphide are formed—*vide supra*. E. F. Anthon observed that hydrated ferrous sulphide precipitates cadmium sulphide from a soln. of **cadmium sulphate**. F. Feigl and co-workers found that ferrous sulphide reacts with a soln. of **mercuric chloride** forming mercuric sulphide and ferrous chloride; and when a cold, sat., ammoniacal soln. of **mercuric cyanide** is evaporated to dryness with precipitated ferrous sulphide, and afterwards calcined, F. W. Schmidt and R. von der Linde observed that ferric oxide remains. E. Schürmann found that **thallium nitrate** and ferrous sulphide partially precipitate some thallium as sulphide. W. O. Hickok observed no reaction with a soln. of **stannous chloride**. E. F. Anthon observed that hydrated ferrous sulphide, and a soln. of **lead nitrate**, with 15 mins'. boiling, precipitate the lead as sulphide. E. F. Anthon, and E. Schürmann observed no precipitate with soln. of **manganese sulphate**. O. Ruff and B. Hirsch studied the reaction with **nickel and cobalt sulphates**. F. A. Eustis represented the reaction with **ferric chloride** by $2\text{FeCl}_3 + \text{FeS} = 3\text{FeCl}_2 + \text{S}$, and said that the reaction is almost complete. E. F. Anthon, E. Schürmann, and O. Ruff and B. Hirsch said that the reaction with ferrous sulphide and soln. of **cobalt nitrate** depends on how long the soln. is boiled; and similarly with soln. of **nickel nitrate**.

Ferrous sulphide unites with other **metal sulphides** to form complex sulphides. F. Warlimont found that **copper sulphide** begins to react with ferrous sulphide when heated in air at 450° to 550° and copper sulphate and ferric oxide are formed. W. Böttger and K. Druschke studied the mutual precipitation of iron and copper sulphides. P. Fischer found that mixtures of ferrous sulphide and **silver sulphide** show a conductivity curve with a maximum and a minimum; and mixtures of ferrous sulphide and **lead sulphide** are non-conducting up to 50 per cent. PbO, and with higher proportions the conductivity rapidly increases. According to E. Diepschlag and E. Horn, the reaction between ferrous sulphide and **ferric oxide** begins at about 500°, and at 800° to 850° the reaction $\text{FeS} + 10\text{Fe}_2\text{O}_3 = 7\text{Fe}_3\text{O}_4 + \text{SO}_2$ is complete; the reduction of the ferrosic oxide to ferrous oxide begins at about 1100°, and the reaction $\text{FeS} + 3\text{Fe}_3\text{O}_4 = 10\text{FeO} + \text{SO}_2$ then occurs. The reaction was also studied by L. Wöhler and co-workers, F. Martin and O. Fuchs, L. L. de Koninck, W. F. Hillebrand and H. N. Stokes, and J. H. L. Vogt. F. Warlimont said that **nickel sulphide** is scarcely attacked by ferrous sulphide at 550°.

Complex salts of ferrous sulphide.—C. Brunner¹⁹ prepared prismatic, bronze crystals of **sodium ferrous sulphide**, $\text{Na}_2\text{S} \cdot 2\text{FeS}$, by calcining a mixture of ferrous oxalate and sodium thiosulphate. H. Freeman observed that when fused with sodium sulphide, iron sulphide forms a complex salt soluble in water. F. Thomas made a few observations on the m.p. of mixtures of ferrous and sodium sulphides, and the results of L. V. Steck and co-workers, for mixtures with over 37 per cent. of ferrous sulphide, are summarized in Fig. 614. The diagram is still incomplete. There is a region between 53 and 73 per cent. iron sulphide in which two liquid phases can form, one being a double compound, probably $\text{FeS} \cdot \text{Na}_2\text{S}$, sat. with iron sulphide, and the other being iron sulphide sat. with a double compound, or some-

FIG. 614.—Equilibrium Curves for the System: Na_2S — FeS .

thing similar to it. One true eutectic is found at 46 per cent. of iron sulphide and 585° . The m.p. of sodium sulphide has been determined as 970° , although its purity was such that the m.p. of pure sodium sulphide can be expected to be slightly higher. According to S. M. Horsch, when hydrogen sulphide is passed over a molten mixture of sodium hydroxide and ferric oxide, **sodium ferrous pentasulphide**, $\text{FeS} \cdot 4\text{Na}_2\text{S}$, is produced; the salt dissolves in water, giving a deep emerald-green

FIG. 615.—Fusion Curves of the System: $\text{FeS}-\text{Cu}_2\text{S}$.

FIG. 616.—Properties of the $\text{FeS}-\text{Cu}_2\text{S}$ alloys.

soln. Its aq. soln., after dialysis, in the absence of air, retains the two sulphides in the proportion given. A conc. soln. on cooling gives a hydrogel, having the composition $\text{Na}_2\text{S} \cdot 2\text{FeS}$, which dissolves in water, giving a black soln., and on adding ammonium chloride to this soln., ferrous sulphide is precipitated. If to this soln., the requisite amount of sodium sulphide is added, it regains the original green colour. R. Schneider found that when potassium ferric sulphide

FIG. 617.—Freezing-point Curves of the System: $\text{Cu}_2\text{S}-\text{FeS}$.

is heated in hydrogen, black crystals of **potassium ferrous sulphide**, $\text{K}_2\text{S} \cdot 2\text{FeS}$, are formed; and K. Preiss obtained needle-like crystals, resembling those of potassium permanganate, by melting together one part of iron filings with ten parts of a mixture of equal proportions of potassium carbonate and sulphur—*vide infra*, complex salts of ferrous sulphide. The products obtained by H. Malfatti may be complex salts of ferric sulphide (*q.v.*), but they have not been definitely established as chemical individuals.

K. Bornemann and F. Schreyer prepared three complexes with copper sulphide by heating mixtures of the two sulphides in an atm. of nitrogen. Their f.p. curve is shown in Fig. 617. P. P. Fedotieff obtained a simple V-curve as illustrated in Fig. 615, showing no evidence of the existence of compounds. The two compounds are only partially miscible in the solid state. O. Reuleaux, and K. Bornemann and H. Schad also made observations on this subject; and H. Tiedemann, and P. P. Fedotieff studied the subject from the point of view of the formation of hair copper. C. B. Carpenter and C. R. Hayward obtained a curve with two branches intersecting at the eutectic at 995° and 68 per cent. FeS ; solid soln. are formed with limits of

observations on this subject; and H. Tiedemann, and P. P. Fedotieff studied the subject from the point of view of the formation of hair copper. C. B. Carpenter and C. R. Hayward obtained a curve with two branches intersecting at the eutectic at 995° and 68 per cent. FeS ; solid soln. are formed with limits of

solubility at 92.5 and 50 per cent. of FeS respectively. Ferrous sulphide melts at 1163° and cuprous sulphide, at 1128°. A transformation occurs in the solid soln. at 950° due to a dimorphic change in the crystal habit of cuprous sulphide. There is a loss of sulphur in the range 15 to 45 per cent. FeS when the mixture is heated above its m.p., and copper is formed. Observations were also made by P. Röntgen, A. Gibb and R. C. Philip, E. Keller, F. H. Edwards, H. O. Hofman and co-workers, A. Baykoff and N. Troutneff, W. Guertler and K. L. Meissner, W. Guertler and O. Reuleaux, C. F. Plattner, C. H. Fulton and I. E. Goodner, J. W. Richards, O. Reuleaux, K. Bornemann and H. Schad, E. L. Larison, E. D. Peters, and F. Frölich. W. Guertler studied the system: Fe-Cu-S. According to G. Tammann and H. Bohner, in the quaternary system: $\text{Cu}_2\text{S} + \text{Fe} \rightleftharpoons \text{FeS} + 2\text{Cu}$, at certain concentrations, mixtures of liquid copper and cuprous sulphide and of iron and copper are immiscible, the diagram shows the existence of an area in which three layers are formed instead of two, one of sulphide and two are metallic. Analysis of the layers formed by melting together equivalent amounts of iron and cuprous sulphide shows that the copper and iron are divided practically equally between the metal and sulphide layers. This corresponds to the very small heat of the forward reaction in the above equation. Manganese or aluminium, the sulphides of which have much higher heats of formation than those of copper or iron, can displace the latter two metals almost completely from the molten sulphide layer. F. H. Edwards measured Shore's hardness, H , the sp. gr., and the e.m.f. of a cell with the alloy and platinum as electrodes and an acid electrolyte. The results are plotted in Fig. 616. Only **cuprous ferrous trisulphide**, $2\text{Cu}_2\text{S} \cdot \text{FeS}$, Fig. 617, is stable at all temp. below the f.p. At 915°, **cuprous ferrous heptasulphide**, $2\text{Cu}_2\text{S} \cdot 5\text{FeS}$, undergoes a transformation, and between 540° and 570°—say 550°—breaks up into ferrous sulphide and the complex trisulphide; while **cuprous ferrous pentasulphide**, $3\text{Cu}_2\text{S} \cdot 2\text{FeS}$, undergoes a change at 180° to 230° forming copper and probably iron disulphides which furnish a solid soln. with the undecomposed compound. P. Ramdohr and O. Oedman described a mineral occurring in minute hexagonal scales at Kaveltorp, Sweden; they called it *vallerite*; and represented it by $\text{Cu}_2\text{Fe}_4\text{S}_7$, or $\text{Cu}_3\text{Fe}_4\text{S}_7$. L. Cambi and L. Szegö, and R. Schneider described **potassium copper ferric sulphide**, $\text{K}_2\text{FeCu}_3\text{S}_4$, which, according to L. Cambi and L. Szegö, has a tetragonal lattice with $a : c = 1 : 1.182$. M. Lefraye described a **cupric ferrous sulphide**, $\text{CuS} \cdot 2\text{FeS}$, or CuFe_2S_3 , from the Katanga copper ores, and it was called *orange borrite*. W. Guertler and E. Lüder studied the formation of **silver ferrous sulphide** in the ternary system: Ag-Fe-S—*vide* silver ferric sulphides. W. Guertler and E. Lüder also studied the system: Ag-Cu-Fe-S. V. Nikitin considered *silver pyrites* is a solid soln. of FeS in AgFeS_2 . J. S. MacLaurin obtained a small yield of **gold ferrous sulphide**, $\text{Au}_2\text{S} \cdot \text{FeS}$, by melting together gold and iron in the presence of sulphur.

W. P. Jorissen and B. L. Ongkiehong studied the limits of the reaction between iron, magnesium, and sulphur. K. Friedrich found that no **zinc ferrous sulphide** is formed when the component sulphides are fused together; the f.p. curve, Fig. 618, shows a eutectic at about 1175°, and 5 per cent. of zinc sulphide. The mineral *marmatite*, described by J. B. J. D. Boussingault, has a composition approximating $3\text{ZnS} \cdot \text{FeS}$. A. Breithaupt described a variety which he called *christophite*, $2\text{ZnS} \cdot \text{FeS}$, from the St. Christophe mine, Breitenbrunn; and J. H. Collins, a similar mineral from St. Agnes, Cornwall. These minerals are to be regarded as ferruginous sphalerites with the ratio $\text{ZnS} : \text{FeS}$ varying from 5 : 1 to 2 : 1. W. F. de Jong said the X-radiograms correspond rather with mixed crystals than with definite compounds. For sphalerite the lattice parameter $a = 5.394 \text{ \AA}$; for marmatite, $\text{Zn}_{0.73}(\text{Fe}, \text{Mn})_{0.27}\text{S}$, $a = 5.415 \text{ \AA}$; and for christophite, $\text{Zn}_{0.66}(\text{Fe}, \text{Mn})_{0.34}\text{S}$, $a = 5.420 \text{ \AA}$. According to F. Ulrich and V. Vesely, the sphalerite from Choléroff has the composition $9\text{ZnS} \cdot \text{FeS}$. For **cadmium ferrous sulphide**, *vide infra*.

W. P. Jorissen and B. L. Ongkiehong studied the limits of the reaction between iron, aluminium, and sulphur. According to M. Houdard, when ferrous sulphide

or pyrites is reduced with aluminium, there is formed **aluminium ferrous sulphide**, $\text{FeS} \cdot \text{Al}_2\text{S}_3$. H. Ditz represented the reactions $2\text{FeS}_2 + 2\text{Al} = \text{Fe} + \text{Al}_2\text{S}_3 \cdot \text{FeS}$, and $4\text{FeS} + 2\text{Al} = 3\text{Fe} + \text{Al}_2\text{S}_3 \cdot \text{FeS}$. J. de Haan observed no formation of a **stannous ferrous sulphide** in his study of the f.p. of the binary system: $\text{SnS}-\text{FeS}$, Fig. 619. The system was also studied by E. Kordes. The mineral *stannite*—7.46, 24—is a **cuprous stannic ferrous sulphide**, $\text{Cu}_2\text{SnFeS}_4$. It is thought that the crystal lattice is of the chalcopyrite type. T. W. Case observed no change in the electrical resistance of stannite on exposure to light. According to K. Friedrich, **lead ferrous sulphide**

FIG. 618. — Freezing-point Curves of the System: $\text{ZnS}-\text{FeS}$.

FIG. 619. — Freezing-point Curves of the System: $\text{SnS}-\text{FeS}$.

FIG. 620. — Freezing-point Curves of the System: $\text{PbS}-\text{FeS}$.

is not formed when the constituent sulphides are melted together. The f.p. curves show a eutectic at 863° , and 70 per cent. PbS . E. Kordes, and W. Guertler and W. Leitgeb studied the system $\text{Fe}-\text{Pb}-\text{S}$. According to M. Gröger, **ferrous chromic sulphide**, $\text{Cr}_2\text{S}_3 \cdot \text{FeS}$, is formed as a black, insoluble compound when a mixture of iron, chromic hydroxide, and sulphur is heated. A black mineral found by J. L. Smith to be associated with troilite in the meteoric stones of Cohahuila, Mexico; Toluca, Mexico; Sevier, Tennessee; and Cranbourne, Australia, was named **daubréelite**—after A. Daubrée. Its composition approximates $\text{FeS} \cdot \text{Cr}_2\text{S}_3$. Its sp. gr. is 5.01, and it is not magnetic. S. Meunier synthesized it by treating at a red-heat an alloy of chromium and iron, chromite, or a mixture of ferrous and chromic chlorides, with hydrogen sulphide. Daubréelite was also studied by A. Brezina, A. Brezina and E. Cohen, L. H. Borgström, A. Lacroix, and F. Zambonini. The chromic oxide found by C. U. Shepard in meteorites, and called *schreibersite*, may have been daubréelite. W. Haidinger called it *shepardite*. For the complex **antimony ferrous sulphide**, *vide* the sulphoantimonates.

FIG. 621. — Freezing-point Curves of the System: $\text{FeS}-\text{MnS}$.

G. Röhl²⁰ studied the f.p. curves of the system: $\text{MnS}-\text{FeS}$, and his results are summarized in Fig. 621. There is a eutectic at 1181° with about 7 per cent. of manganous sulphide. The microscopic evidence indicates that with about 40 per cent. of manganous sulphide, **manganese ferrous pentasulphide**, $3\text{FeS} \cdot 2\text{MnS}$, melting at 1365° , is formed. An unlimited series of solid soln. are formed with the dubious compound $\text{Fe}_3\text{Mn}_2\text{S}_5$ and manganous sulphide. It was not possible to measure the

solidus curve accurately—*vide supra*, the desulphurization of iron by manganese. Z. Shibata found that the two sulphides mix in all proportions in the fused state, and partially in the solid state. There is a eutectic at 1164° and 6.5 per cent. of MnS . The binary system: $\text{FeS}-\text{MnS}$ was studied by D. M. Levy,

and G. Röhl. The results were summarized by C. Benedicks and H. Löfquist, in Fig. 622, on the assumption that no compound is formed; and their reconstruction for the system: Fe-Mn-S, based on the observations of J. E. Stead, A. Ledebur,

FIG. 622.—The Equilibrium Curves of the Binary System: FeS-MnS.

FIG. 623.—The Equilibrium Curves of the Ternary System: Fe-Mn-S.

G. Hilgenstock, H. le Chatelier and A. Ziegler, and E. Schütz, as well as those of M. Levin and G. Tammann, G. Rümelin and K. Fick, H. Esser and P. Oberhoffer, A. Westgren and G. Phragmen, and E. C. Bain on the Fe-Mn system, are indicated in Fig. 623. G. Röhl estimated that solid manganese sulphide dissolves 60 per cent. of FeS, and D. M. Levy, 50 per cent. The solid soln. (Fe,Mn)S is supposed to have the limit 55 per cent. FeS in Fig. 622. Solid ferrous sulphide dissolves very little manganous sulphide. The eutectic FeS-(Mn,Fe)S is at 1181° and 7 per cent. MnS. G. Röhl found that there is a ternary eutectic in the system: Fe-Mn-S, consisting of iron and the two sulphides—4 per cent. MnS. The m.p. of the ternary eutectic is about 980°, a little below 985° the binary eutectic Fe-FeS. There is a region of immiscibility. C. Benedicks and H. Löfquist also constructed space-models of the system. The quadratic diagram, Fig. 624, represents C. Benedicks and H. Löfquist's reconstruction of the quaternary system: MnS-MnO-FeS-FeO. It has not been confirmed by observation; but isolated observations on the system have been reported by C. R. Wohrmann, and M. Matwieff.

FIG. 624.—The Quaternary System: FeO-MnO-FeS-MnS.

§ 41. Ferric Sulphide

J. L. Proust,¹ and C. F. Bucholz and A. F. Gehlen reported **ferric sulphide**, Fe_2S_3 , to be formed by heating iron or ferrous sulphide with sulphur, in a non-oxidizing atmosphere, until the excess of sulphur is expelled. C. F. Rammelsberg recommended a temp. between 450° and 500° , and R. Scheuer, 450° . Similar results were obtained by L. Gedel. J. J. Berzelius recommended passing hydrogen sulphide over hydrated ferric oxide, at a temp. below 100° , as long as water continues to be formed. E. Brescius, and M. C. Abderhalden observed that if the gas and solid are quite dry, no action occurs under these conditions, and if moisture be present, the conversion of the oxide to ferric sulphide is slow and incomplete. C. F. Rammelsberg could obtain only a mixture of sulphide and oxide by J. J. Berzelius' process, and if a higher temp. be employed pyrrhotite is formed. It is possible that the alleged ferric sulphide prepared by these methods is really a solid soln. of ferrous sulphide and sulphur—*vide supra*. L. J. Proust's product was magnetic; J. J. Berzelius', non-magnetic. R. Juza and W. Biltz did not find this compound formed in the reaction: $\text{FeS}_2 \rightarrow \text{FeS} + \text{S}$ —*vide infra*.

The question whether the product obtained by the action of hydrogen sulphide on ferric oxide or hydroxide is ferric sulphide or a mixture of ferrous sulphide and sulphur has been the subject of much discussion. A. Wagner, L. Gedel, and E. T. Allen and co-workers regard the product as a mixture of ferrous sulphide and sulphur. G. Gallo observed that ferric sulphide is formed in the action of hydrogen on pyrites at about 228° to 230° . W. Moldenhauer and E. Mischke said that the hydrogen sulphide reduces about two-thirds of the ferric-iron to the ferrous state, and the product is not a mixture of ferrous and ferric sulphides, but rather a compound of the two sulphides. Some consider that a veritable ferric sulphide is formed: $\text{Fe}_2\text{O}_3 + 3\text{H}_2\text{S} = \text{Fe}_2\text{S}_3 + 3\text{H}_2\text{O}$. W. Mecklenburg and V. Rodt modified J. J. Berzelius' process by suspending the thoroughly washed, hydrated ferric oxide in water, removing air by a current of carbon dioxide, and passing hydrogen sulphide into the liquid until no more gas is absorbed. After standing 12 hrs., the black precipitate is filtered off, with the exclusion of air, since oxidation readily occurs. It can then be dried over phosphoric oxide in vacuo. G. Weyman, and W. A. Dunkley said that the reactivity of the hydrated oxide depends more on its molecular state than on the amount of moisture present. An oxide which has been heated between 100° and 600° takes up the theoretical amount of gas on cooling; but not so with the oxide heated to 650° or 800° . An oxide with 5 to 8 per cent. water was found by G. H. Gemmel to react best, and this at 38° . J. C. Bell studied

the reactivity of the differently hydrated oxides: and L. T. Wright, P. Hausknecht, R. Scheuer, L. A. Sayce, and T. G. Pearson and P. L. Robinson, the effect of temp. on the absorption of gas. F. Gieseler considered this the best method to use for preparing ferric sulphide. If the oxide is heated during the absorption, some sulphate may be formed. H. Deicke, R. Cox, and E. Brescius showed that an excess of sulphur in the product, assumed to be ferric sulphide, may be due to oxidation by atm. air. The use of ferric oxide in place of lime for absorbing hydrogen sulphide from coal-gas was recommended by E. Heard, and W. R. Bowditch near the beginning of the 19th century. The subject was discussed by G. Anderson, H. Brückner, K. Burkheiser, A. A. Croll, B. Dunglinson and J. M. Gonder, R. Geipert, M. Hempel, F. C. Hills, R. Laming, G. Löwe, F. E. Evans, A. Buhe, and N. H. Schilling.

According to L. T. Wright, **hydrated ferric sulphide**, $\text{Fe}_2\text{S}_3 \cdot n\text{H}_2\text{O}$, is formed when hydrated ferric oxide is moistened, or suspended in water, and treated with hydrogen sulphide for several hours—preferably in the absence of air. It was thus prepared by J. J. Berzelius who added that the transformation proceeds at ordinary temp. with a slight evolution of heat, but it is best to employ the heat of a water-bath towards the ends of the operation. The water can be expelled from the hydrate by keeping it in vacuo, preferably over phosphorus pentoxide. The anhydrous sulphide thus obtained is pyrophoric if suddenly exposed to air; otherwise it is quite stable. According to F. Feigl and E. Bäcker, when the washed precipitate of empirical composition Fe_2S_3 , formed by precipitation of a tartrate-containing solution of ferric salt with ammonium sulphide, reacts in neutral solution with mercuric and cadmium salts, it behaves as ferrous and ferric sulphide, respectively. This suggests that the substance is a mixture of the valency isomerides $\text{S} : \text{Fe.S} : \text{Fe} : \text{S}$ and $\text{FeS} : \text{FeS}_2$. H. Krepelka and W. Podrouzek showed that the composition of the precipitate depends on the conditions of precipitation, and similar conditions are valid for the mercaptides of iron. F. Feigl and E. Bäcker found that soln. of ferric salts give ferrous mercaptide with ethyl mercaptan. When, however, the concentration of ferric ion is depressed by addition of tartrate and such a soln. is run slowly into an alcoholic soln. of ethyl mercaptan, **ferric ethyl mercaptide** results. When a solution of ferric chloride is added to a soln. of barium sulphide, or when freshly-precipitated ferric sulphide is treated with a soln. of barium sulphide, a substance approximating to the composition BaFe_2S_4 is obtained. This was also prepared by H. Malfatti. The compound reacts with mercuric salts as the original ferric sulphide. It is very unstable and is decomposed by mere washing with water. The compounds described by H. Malfatti are probably mixed sulphides rather than thioferrites. When moist ferric hydroxide is treated with ammonium sulphide, the sulphide formed has the composition Fe_2S_3 , whilst that obtained by precipitation from a soln. of ferric salt containing tartrate, has the initial composition $\text{Fe}_2\text{S}_3 \cdot (\text{NH}_4)_2\text{S}$.

L. Gedel added that in the purification of coal-gas, the reaction can be represented: $2\text{Fe}(\text{OH})_3 + 3\text{H}_2\text{S} = \text{Fe}_2\text{S}_3 + 6\text{H}_2\text{O}$; the formation of iron disulphide is prevented if traces of ammonia be present. Hydrogen sulphide acts on the dried hydrate $\text{Fe}_2\text{O}_3 \cdot \text{H}_2\text{O}$, in the presence of hydrochloric acid, to form ferrous sulphide, sulphur, and iron disulphide; while hydrogen sulphide mixed with a little ammonia converts hydrated ferric oxide into ferric sulphide. If air be present along with hydrogen sulphide containing traces of hydrogen chloride, it has no influence on the production of iron disulphide.

As indicated in connection with the preparation of hydrated ferrous sulphide, J. J. Berzelius, and H. N. Stokes showed that hydrated ferric sulphide is formed when a soln. of a ferric salt is added to an excess of ammonium or alkali sulphide soln., but if the alkali sulphide be added to the ferric salt in excess, a mixture of ferrous sulphide and free sulphur is formed. H. N. Stokes showed that if the reaction occurs in the presence of zinc hydroxide, the reaction $\text{Fe}_2\text{S}_3 + 3\text{Zn}(\text{OH})_2 = 2\text{Fe}(\text{OH})_3 + 3\text{ZnS}$ occurs rapidly in the cold, and instantly on boiling. Alkali

polysulphides precipitate ferrous salts as ferric sulphide. L. A. Sayce found that ferric sulphide is formed by the action of hydrogen sulphide on ferric oxide (*q.v.*). L. Gedel added that a black mixture of ferrous sulphide is formed when ferric chloride is treated with ammonium sulphide in sufficient quantity for all the soln. to remain acidic in virtue of the hydrolysis of the ferric salt; but if enough ammonium sulphide is added to make the soln. of ferric chloride alkaline, the dried precipitate contains ferric sulphide associated with small proportions of ferrous sulphide, sulphur, and iron disulphide. Ferric sulphide is produced when ferrous sulphide is treated with ammonium polysulphide; and if a small proportion of ammonium sulphide be added to an alkaline soln. of a ferric salt—obtained by adding ammonia to a soln. of ferric chloride in tartaric acid—ferric sulphide is formed. T. L. Phipson stated that the hydrate is produced when ferric chloride is added to ammonium sulphide containing a little sodium hypochlorite, or when a ferric salt containing free chlorine or hypochlorite is precipitated by ammonium sulphide. The ammonium sulphide soln. should have acquired by age the ordinary yellow tint. The analysis corresponds with $\text{Fe}_2\text{S}_3 \cdot 1\frac{1}{2}\text{H}_2\text{O}$.

A. Dumansky and A. Yakovléeff prepared **colloidal ferric sulphide** by saturating a hot, 60 per cent. soln. of tartaric acid with washed ferric hydroxide made alkaline with 25 per cent. aq. ammonia, diluting the soln. with 4 to 32 times its vol. of water, and adding an aq. soln. of hydrogen sulphide—0.00369 grm. per c.c. Aq. ammonia hastens coagulation. The sulphide sol is negatively charged, it is easily coagulated by salts, and when warmed it deposits ferric hydroxide and sulphur. J. C. Witt obtained a black amorphous substance by the action of sodium sulphide on ferric oxide, and on washing out the sodium sulphide, there is formed a reversible, green, colloidal soln. with less than 0.07 grm. of iron per litre. J. Casares studied the colloid; and P. Lal and P. B. Ganguly, the action of ultra-violet light on the hydrosol.

The colour of ferric sulphide prepared in a dry way is grey with a yellow tinge which is not so pronounced as in the case of iron disulphide; and J. J. Berzelius added that if it be warmed in vacuo, the yellow colour and lustre become more pronounced. The ferric sulphide prepared by the wet processes is black. T. L. Phipson said that the colour of the hydrate is dark emerald green, and, when collected on a filter, it appears black. The green colour becomes apparent after drying if the powder be ground up with, say, chalk. L. Playfair and J. P. Joule found the sp. gr. to be 4.246; and C. F. Rammelsberg, 4.41. F. Gieseler gave 4.286 for the sp. gr. of ferric sulphide at $25^\circ/4^\circ$; and he calculated 48.5 for the mol. vol., and 11.4 for the at. vol. of the contained sulphur; this gave 25 per cent. for the contraction during the formation of this compound. M. Kimura and M. Takewaki observed that ferric sulphide absorbs ultra-violet rays. J. J. Berzelius said that the sulphide is not magnetic. The dry sulphide is stable in dry air, but when moist, it soon becomes converted into ferric oxide and sulphur. According to V. Rodt, and W. Mecklenburg and V. Rodt, when exposed to air in the presence of alkaline substances, ferric sulphide becomes light yellow owing to the separation of free sulphur, and L. Gedel represented the reaction: $2\text{Fe}_2\text{S}_3 + 3\text{O}_2 = 2\text{Fe}_2\text{O}_3 + 3\text{S}_2$. V. Rodt said that no FeS_2 is formed. The regeneration of the spent ferric oxide, from the hydrogen sulphide purification of coal-gas, by exposure to moist air was discussed by J. C. Bell, A. Buhe, K. Burkheiser, R. Cox, A. A. Croll, H. Deicke, F. E. Evans, E. Heard, P. Hausknecht, F. C. Hills, R. Laming, G. Löwe, W. Mecklenburg and V. Rodt, G. H. Palmers, V. Rodt, E. Schilling, N. H. Schilling, A. Wagner, and L. T. Wright. K. Jellinek and H. Gordon observed that ferric sulphide is almost insoluble in water, and gave $[\text{Fe}^{+++}]^2[\text{S}^{--}]^3 = 10^{-88}$ for the solubility product. H. N. Stokes found that at 100° , ferric sulphide readily hydrolyzes into ferric hydroxide and hydrogen sulphide. E. Filhol and J. Melliès found that with iodine, ferric sulphide forms ferrous iodide. J. J. Berzelius said that dil. hydrochloric or sulphuric acid acts on ferric sulphide forming hydrogen sulphide, a ferric salt, and iron disulphide; but L. Gedel, and E. Bressius represented the reaction

with hydrochloric acid by the equation: $\text{Fe}_2\text{S}_3 + 4\text{HCl} = 2\text{FeCl}_2 + 2\text{H}_2\text{S} + \text{S}$. If some pyrrhotite be present, iron disulphide, ferrous chloride, and hydrogen sulphide are formed. T. L. Phipson stated that ferric sulphide dissolves in hydrochloric acid with effervescence, producing immediately ferric chloride in spite of the abundance of hydrogen sulphide present. According to V. Rodt, and W. Mecklenburg and V. Rodt, if moist hydrated ferric sulphide be exposed to hydrogen sulphide in the absence of air, it is transformed into a mixture of ferrous sulphide and iron disulphide: $\text{Fe}_2\text{S}_3 = \text{FeS} + \text{FeS}_2$. This transformation may take place slowly at ordinary temp., but it occupies only a few hours at 60° . T. L. Phipson said that it is appreciably soluble in water containing some ammonia, and separates from soln. as ammonia escapes; it is more readily soluble in water containing free ammonia, it is even more soluble in alcoholic ammonia forming in each case a clear, green soln. which can be filtered. It is only slightly soluble in a mixture of ammonium sulphide and hypochlorite; nor is it more soluble in either of these substances alone. R. F. Weinland and L. Storz observed that with sodium arsenite, ferric sulphide forms ferric hydroxide and hydrogen sulphide; and L. T. Wright, and T. G. Pearson and P. L. Robinson, that a hot soln. of potassium cyanide forms potassium ferrocyanide. E. Jordis and E. Schweizer found that when extracted with carbon disulphide for many days, some sulphur is removed from ferric sulphide; and similarly also with alcohol, or benzene as solvents. L. T. Wright observed that soln. of copper sulphate and silver nitrate are decomposed by ferrous sulphide. H. N. Stokes showed that an ammoniacal soln. of zinc hydroxide reacts: $\text{Fe}_2\text{S}_3 + 3\text{Zn}(\text{OH})_2 = 2\text{Fe}(\text{OH})_3 + 3\text{ZnS}$; a similar result was found by H. Malfatti with ammoniacal cadmium sulphate; but F. Feigl and co-workers represented the reaction: $\text{Fe}_2\text{S}_3 + 2\text{CdSO}_4 = 2\text{CdS} + \text{S} + 2\text{FeSO}_4$; and H. Malfatti obtained ferric hydroxide and lead sulphide with a soln. of lead acetate containing some potassium hydroxide and glycerol. F. Feigl and co-workers found that the reaction with mercuric chloride gives a ferrous salt: $\text{Fe}_2\text{S}_3 + 2\text{HgCl}_2 = 2\text{HgS} + \text{S} + 2\text{FeCl}_2$, and this favours the assumption that the formula of ferric sulphide is $\text{FeS} \cdot \text{FeS}_2$, otherwise the reaction: $\text{Fe}_2\text{S}_3 + 3\text{HgCl}_2 = 3\text{HgS} + 2\text{FeCl}_3$ would be anticipated. A number of complex salts occur in nature as minerals or mixtures of minerals.

H. Malfatti showed that there is the probability that when a soln. of ferric chloride is treated with an excess of ammonium sulphide, $(\text{NH}_4)_2\text{S}$, **ammonium ferric sulphide**, or **ammonium sulphoferrite**, NH_4FeS_2 , is formed. After washing out the ammonium salts, or long standing in water, or warming with water, a green soln. is formed under conditions where ferric sulphide alone is not dissolved. The green soln. is probably the peptized colloid. H. Malfatti similarly obtained **potassium ferric sulphide**, or **potassium sulphoferrite**, KFeS_2 , by the action of hydrogen sulphide on a mixture of hydrated ferric oxide, and an alcoholic soln. of potassium hydroxide. The black product is decomposed by water to form potassium sulphide and gelatinous, hydrated ferric sulphide. R. Schneider obtained the complex salt, KFeS_2 , by melting powdered iron with potassium carbonate and sulphur, and leaching the cold product with water. He represented the constitution of the salt by the formula:

The purple-brown, acicular crystals are probably rhombic, and have a sp. gr. of 2.563. If air be excluded, the salt can be heated without decomposition, but in air, potassium sulphate, ferric oxide, and sulphur dioxide are formed. J. Thugutt could not prepare this salt. By heating for 70 hrs. at 197° to 200° , 4 grms. of potassium hydroxide, 3.17 grms. of hydrated ferric oxide, and 40 c.c. of water, sat. with hydrogen sulphide, he obtained a product of the composition $3\text{K}_2\text{S} \cdot \text{Fe}_3\text{S}_9 \cdot 22\text{H}_2\text{O}$. R. Schneider's salt is rapidly decomposed by dil. acids with the formation of hydrogen sulphide, and the deposition of sulphur. When heated in hydrogen,

$K_2Fe_2S_3$ is formed. J. Milbauer obtained the salt $KFeS_2$ by heating ferric oxide with potassium thiocyanate at 400° . The crystals of potassium sulphoferrite, $KFeS_2$, were found by H. O'Daniel to be hexagonal, with the axial ratio $a : c = 1 : 0.3939$, and the X-radiograms correspond with a lattice having $a = 13.03$ Å., and $c = 5.40$ Å., so that $a : c = 1 : 0.4144$. The sp. gr. is 2.66, and if there are eight molecules per unit cell, the calculated sp. gr. is 2.642.

R. Schneider prepared **sodium ferric sulphide**, or **sodium sulphoferrite**, $NaFeS_2 \cdot 4H_2O$, by the method he used for the potassium salt. J. Thugutt obtained it by heating for 76 hrs. at 197° to 200° a mixture of 6 grms. of sodium hydroxide, 2.77 grms. of hydrated ferric oxide, and 40 c.c. of water sat. with hydrogen sulphide. H. Fincke studied the action of ferrous sulphide on fused sodium sulphide. According to W. Mecklenburg and V. Rodt, sodium ferric sulphide occurs in the black ash of the Leblanc process for soda, and a convenient method of preparing it is to add a soln. of a ferric salt to an excess of a soln. of sodium sulphide, or to treat a soln. of a ferrous salt with an excess of sodium polysulphide. F. Faktor obtained the anhydrous salt by heating four parts of sodium thiosulphate with one part of iron; it forms dark green, needle-shaped crystals, but loses its crystalline structure on exposure to the air, becoming voluminous, and finally forming a brownish-black powder which gives a dark green soln. in water and evolves hydrogen sulphide when treated with hydrochloric acid. The same amorphous substance may also be prepared by melting sodium thiosulphate with iron at low temp. Sodium iron sulphide is insoluble in water and when heated forms the oxide; by the action of conc. hydrochloric acid, hydrogen sulphide and sulphur are liberated, and when boiled with soln. of potassium cyanide, potassium ferrocyanide is formed. The sodium and potassium salts differ in many ways. Their behaviour towards a soln. of silver nitrate, for instance, is symbolized: $K_2Fe_2S_4 + 2AgNO_3 = 2KNO_3 + 2AgFeS_2$; and $Na_2Fe_2S_4 + 4AgNO_3 = Ag_4FeS_4 + 2NaNO_3 + Fe(NO_3)_2$. The $Fe_2S_4^{--}$ ions may break up into $Fe^{--} + FeS_4^{----}$ ions, so that the ionization of the complex ferric sulphides may proceed: $M_2Fe_2S_4 \rightleftharpoons 2M^{+} + Fe_2S_4^{--} \rightleftharpoons 2M^{+} + Fe^{--} + FeS_4^{----}$. Soln. of the more soluble salt—e.g., the sodium salt—contain more FeS_4^{----} ions than that of the less soluble salt—e.g., the potassium salt. Hence the different products obtained by the addition of silver nitrate to the aq. soln.

A series of complex **copper ferric sulphides** associated, maybe, with ferrous sulphide, occurs as minerals. For instance:

Chalcopyrite, or copper pyrites	$CuFeS_2$, or $Cu_2S \cdot Fe_2S_3$
Barnhardite	$Cu_4Fe_2S_6$, or $2Cu_2S \cdot Fe_2S_3$
Bornite	Cu_3FeS_3 , or $3Cu_2S \cdot Fe_2S_3$
Barracanite	$CuFe_2S_4$, or $CuS \cdot Fe_2S_3$
Chalcopyrrhotite	$CuFe_2S_3$, or $2FeS \cdot CuS \cdot Fe_2S_3$
Chalmersite (rhombic), cubanite (cubic)	$CuFe_2S_3$, or $Cu_2S \cdot Fe_4S_5$

There is no general agreement even as to the composition of most of them. Different views may be favoured as to the constitution of these complex salts. P. Groth² suggested that they are salts of three **sulphoferric acids**, namely:

Disulphoferric acid, $HFeS_2$.	Trisulphoferric acid, H_3FeS_3 .	Pentasulphodiferric acid, $H_4Fe_2S_5$.
Chalcopyrite, $Cu'FeS_2$.	Bornite, $Cu_3'FeS_3$.	Barnhardite, $Cu_4'Fe_2S_5$.
Barracanite, $Cu''(FeS_2)_2$.	Cubanite, $Fe''Cu'FeS_3$.	
	Chalcopyrrhotite, $(Cu'', Fe'')(FeS_3)_2$.	

The term *χαλκίτης* was used for the copper ore of Cyprus, by Aristotle, about 400 B.C., and apparently also by Dioscorides, in his *De materia medica* (5. 89), in the first century; whilst the term *πυρίτης*, and *pyrites* was also used by Dioscorides, and by Pliny, in his *Historia naturalis* (36. 30), written in the first century of our era. It is also evident that these writers included copper-pyrites under the name *pyrites*. G. Agricola,³ and C. Gesner distinguished copper-pyrites from ordinary pyrites (*q.v.*) by calling the former *Geekis*, or *Kupferkis*; and

J. F. Henckel said that **chalcopyrite** is a good distinctive name for the ore. The same term was used by F. S. Beudant, and J. G. Wallerius, whilst W. H. Miller proposed the term *towanite*—from its occurrence in Huel Towan, Cornwall.

A mineral, more bronze-like than chalcopyrite, was found by A. Breithaupt amongst the copper ores of Plauen, Voigtland, and elsewhere. It was called *homichlin*—from *ομιχλη*, a cloud. It occurs in tetragonal, octahedral crystals, or else massive. Its sp. gr. is 4.472–4.480, and its hardness is 4 to 5. Its composition is close to that of chalcopyrite. It was analyzed by F. Richter. J. D. Dana identified it with barnhardite; C. F. Rammelsberg, with bornite; and G. A. Kenngott, and P. Groth and K. Mieleitner, with chalcopyrite. It may be chalcopyrite partly altered to bornite.

Analyses were reported, in the early days, by R. Chenevix,⁴ A. Gueniveau, R. J. Häüy, A. Breithaupt, C. C. von Leonhard, M. V. Hartwall, etc. Other analyses were reported by H. Stölting, P. Jannasch, T. Haege, H. Laspeyres, A. von Kalcinszky, L. Fletcher, A. d'Achiardi, I. Domeyko, J. L. Soubeiran, B. Blount, C. A. Joy, P. Geijer, P. J. Shenon, E. Bechi, D. Forbes, C. D. Pilide, A. Raimondi, J. H. Collins, F. J. Malaguti and J. Durocher, G. T. Prior, A. Lacroix, P. Pilipenko, etc. The results agree with the formula CuFeS_2 mixed with more or less pyrite. Chalcopyrite sometimes contains gold and silver. A. Dieseldorff, for instance, found the mineral from Wortupa, South Australia, to be comparatively rich in gold. C. W. Dickson observed platinum in a sample from Sudbury. Thallium (*q.v.*) is often present; and C. F. Rammelsberg mentioned the presence of traces of selenium. A. de Gramont discussed the constituents revealed by the spark spectrum.

R. Phillips, and H. Rose represented the composition of the mineral by the formula: CuFeS_2 ; and H. Rose showed that the assumption that it is constituted as a **cuprous ferric disulphide**, or **cuprous sulphoferrite**, $\text{Cu}_2\text{S} \cdot \text{Fe}_2\text{S}_3$, or CuFeS_2 , agrees better with the facts than does the assumption made by R. Phillips that it is constituted $\text{CuS} \cdot \text{FeS}$. G. Rose, and P. Berthier also adopted this hypothesis, and A. Knop showed that this formula, $\text{Cu}_2\text{S} \cdot \text{Fe}_2\text{S}_3$, is more in accord with the behaviour of the mineral towards hydrochloric acid. C. F. Rammelsberg at first favoured R. Phillips' hypothesis, but later, in view of R. Schneider's synthesis from cuprous chloride, and potassium ferric sulphide, P. Groth regarded it as the cuprous salt of a sulphoferric acid, $\text{Cu}(\text{FeS}_2)'$. F. Beijerinck did not favour this hypothesis, but J. Beckenkamp did. T. T. Read, and L. P. Morgan and E. F. Smith titrated a soln. of the mineral with potassium permanganate, and considered that the iron is present in the ferrous, not ferric state, and they suggested that chalcopyrite is a marcasite, with part of the iron replaced by copper. E. C. Sullivan, and H. N. Stokes did not agree. M. Legraye, and A. Laitakarl discussed the formation of copper pyrites.

C. L. Burdick and J. H. Ellis found that the space-lattice of chalcopyrite, Fig. 625, is tetragonal with the axial ratios $a : b : c = 1 : 1 : 0.985$. The iron and

FIG. 625.—Space-Lattice of Chalcopyrite.

copper atoms are located so that they together form a face-centred tetragonal lattice, the planes perpendicular to the tetragonal axis being made up alternately of copper atoms alone and iron atoms alone. The sulphur atoms are located on a similar face-centred lattice with the planes of the sulphur atoms lying midway in all three of the axial directions between the planes of the iron and copper atoms. The subject was also investigated by R. and N. Gross, who regarded chalcopyrite as having the same general character as dolomite. F. Rinne considered magnetite, FeFe_2O_4 , and chalcopyrite, $\text{Cu}_2\text{Fe}_2\text{S}_4$, to be isometric. L. Pauling and L. O. Brockway found the unit cell had 4 mols. of CuFeS_2 ; that $a = 5.24 \text{ \AA.}$, and $c = 10.30 \text{ \AA.}$; the closest distance of copper and sulphur atoms is 2.32 \AA. , and of the iron and sulphur atoms, 2.20 \AA. ; and they infer that the atoms have no

fixed valencies, but fluctuate between $\text{Cu}'\text{Fe}'''\text{S}_2$ and $\text{Cu}''\text{Fe}''\text{S}_2$. H. O'Daniel studied the subject.

Chalcopyrite and bornite are probably of magnetic origin. They are widely disseminated minerals which occur in metallic veins and pockets, and in contact zones in gneiss and crystalline schists, and occurrences in serpentinized rocks have been noted by B. Lotti,⁵ R. Beck and W. von Fircks, and W. H. Weed; in dioritic rocks, by A. Schenck; and in pegmatite, by J. F. Kemp, and J. Catharinet. It occurs as impregnations or replacements in secondary rocks. It is frequently associated with iron pyrites, pyrrhotite, arsenical pyrites, siderite, tetrahedrite, bornite, fahlerz, sphalerite, chalcocite, and sometimes with pentlandite. This subject was discussed by S. G. Lasky, C. Lausen, O. Mügge, P. J. Shenon, A. Sadebeck, O. von Huber, H. W. Turner and A. F. Rogers, K. Schlossmacher, F. Klockmann, H. Schneiderhöhn, M. L. Huggins, W. H. Newhouse, P. Ramdohr, G. M. Schwartz, P. Erimesco, and M. Brinkmann. F. Zambonini inferred that the chalcopyrite of Bocca nel Pigna, Vesuvius, was formed by the action of hydrogen sulphide on soln. of copper and iron chlorides. A. Sadebeck described pseudomorphs of chalcopyrite after fahlerz; P. von Jereméeff, after chalcocite; F. Sandberger, after galena; H. A. Miers, after bournonite; E. Döll, after cuprite; G. N. Maier, and A. Arzruni, after magnetite; H. A. Miers, bismuthinite; and J. R. Blum, after fossils—like ammonites, brachiopods, snails, and fish remains.

J. F. L. Hausmann observed chalcopyrite in the masonry of a roasting furnace at Goslar; A. Reich, in the hearth of a reverberatory furnace at Halsbrücke; A. Reuss, and F. Stolba, in the blast-furnace products near Trautenau; B. von Cotta, and C. W. C. Fuchs, in a furnace of the Muldener Hütte, near Freiberg, etc.; F. Gonnard, in a glass furnace at Lyon; and A. N. Winchell, in a furnace in Butte, Montana. A. Daubrée observed the formation of chalcopyrite, chalcocite, bornite, and tetrahedrite on Roman bronzes exposed to the thermal sulphuretted waters of Bagnères-de-Bigorre, Mer-de-Flines, and Bourbonne-les-Bains; and C. A. de Gouvenain noted that Roman coins exposed to the waters of Bourbon l'Archambault were crusted with chalcopyrite. F. Klockmann also noted the formation of the chalcopyrite in the copper tubes carrying the thermal waters near Pest; whilst E. Chuard observed that bronze implements, from the Swiss lake dwellings, were covered with a thin layer of a kind of stanniferous chalcopyrite.

J. Fournet obtained chalcopyrite by simply fusing a mixture of copper sulphide and pyrite. H. de Sénarmont observed that when a soln. containing ferrous and cuprous chlorides, sodium polysulphide, and an excess of sodium hydrocarbonate is heated to 250° , an amorphous chalcopyrite is formed. C. Doelter gently heated a mixture of copper and ferric oxide in the molar proportions 2 : 1 in a current of hydrogen sulphide, and obtained chalcopyrite. E. G. Zies and co-workers observed that when heated in a sealed tube with a soln. of cupric sulphate, pyrrhotite is converted into chalcopyrite and bornite. R. Schneider agitated a faintly ammoniacal soln. of cuprous chloride, eq. to 0.455 gm. Cu_2O , with a gram of potassium ferric disulphide until the remaining liquid no longer contained copper. Crystals of chalcopyrite were thus obtained, and the mode of preparation shows that the reaction is probably symbolized: $\text{K}_2\text{S} \cdot \text{Fe}_2\text{S}_3 + \text{Cu}_2\text{Cl}_2 = 2\text{KCl} + \text{Cu}_2\text{S} \cdot \text{Fe}_2\text{S}_3$. This reaction is regarded as a demonstration that the substance with the empirical formula CuFeS_2 contains cuprous copper and ferric iron, the argument, to be conclusive, requires a demonstration that the cuprous sulphide is not oxidized by the ferric sulphide. S. W. Young and N. P. Moore found that chalcocite in a soln. of potassium sulphide, or in an aq. soln. of hydrogen sulphide, forms a colloidal soln. of copper sulphide which passes into chalcopyrite when in contact with ferrous sulphate, colloidal ferric sulphide or magnetite.

The colour of chalcopyrite is brass-yellow with a tinge of green; and it is often tarnished or iridescent, when it has been called *peacock ore*—this ore occurs in Cornwall. The streak is black, and according to J. L. C. Schroeder van der Kolk,⁶ the powder is violet. The microstructure and the optical properties of polished

surfaces were examined by H. Schneiderhöhn. J. B. L. Romé de l'Isle, and R. J. Haüy thought that the crystals belonged to the cubic system, although J. F. Henckel had previously observed quadratic pyramids which formed equi-angled triangles. A. Breithaupt said that the crystals do not belong to the cubic system, and this was confirmed by C. C. von Leonhard, and R. Phillips. J. Beckenkamp said that the crystals from Arakawa are rhombic pyramids; according to W. Haidinger, the crystals are pseudo-cubic, being really tetragonal, with the axial ratio $a : c = 1 : 0.98525$; V. Goldschmidt gave $1 : 1.3933$; and G. T. Prior, $1 : 0.9853$. W. Haidinger's results were confirmed by A. Sadebeck, and N. von Kokscharoff. C. L. Burdick and J. H. Ellis' space-lattice agreed with the ratio $a : c = 1 : 0.985$. The mineral may occur massive and compact—a reniform or botryoidal variety, with a smooth brassy appearance, is called *blistered copper ore*. Chalcopyrite may also occur in crystals commonly tetrahedral with the sphenoidal (111)-faces large, dull, or oxidized, and diagonally striated; the $(\bar{1}\bar{1}1)$ -faces may be small, brilliant, and neither oxidized nor striated; whilst the scalenohedral and other faces are often prominent, and often striated parallel with the (111)-intersection. The sphenoidal and other faces may be also striated. Observations on the crystals were made by O. Luedecke, J. S. Stevenson, V. Goldschmidt and R. Schröder, P. Groth, B. Mauritz, G. Tschermak, J. W. Gruner, A. Himmelbauer, J. Königsberger, G. Flink, V. Goldschmidt, B. Mauritz, P. P. Pilipenko, V. Dürrfeld, M. Ungemach, A. S. Russell, H. Mayer, T. Haegi, G. Cesaro, G. vom Rath, J. Beckenkamp, L. Souheur, L. Tokody, H. Baumhauer, F. Sandberger, A. Frenzel, C. F. Naumann, J. F. Oebike, R. B. Hare, A. Franzenau, A. Lévy, L. Buchrucker, R. P. Greg and W. G. Lettsom, W. J. Lewis and A. L. Hall, S. L. Penfield, and N. W. and M. J. Buerger. According to L. Fletcher, twinning occurs (i) about the (111)-plane with the composition face a penetration twin which may be perpendicular to (111), and sometimes repeated as a fiveling; (ii) about the twinning plane and composition face (101), often in repeated twins; and (iii) the twinning plane (110), twinning axis c , and complementary penetration twins; whilst (iv) twinning of pseudo-rhombohedral symmetry is rare. The (201)-cleavage is sometimes distinct, and (001), indistinct. M. J. Buerger, and O. Mügge studied the deformation of crystals by pressure. L. Tokody, Z. Toborffy, and A. Himmelbauer studied the corrosion figures. W. Fackert recommended a mixture of 2.5 vols. nitric acid of sp. gr. 1.2 with 4 vols. hydrochloric acid of sp. gr. 1.19, 10 vols. of water, and a "pinch" of potassium chlorate. P. Ramdohr, W. H. Newhouse, J. W. Gruner, and G. M. Schwartz, investigated **intergrowths** of bornite with stannite, pyrrhotite, cubanite, and chalcocite, and C. Lausen, of chalcopyrite with niccolite.

D. Forbes gave 4.185 for the sp. gr. of chalcopyrite; T. Haegi, 4.301; J. Joly, 4.143; G. T. Prior, 4.170; A. Lacroix, 4.100; P. P. Pilipenko, 4.120; E. Madelung and R. Fuchs, 4.1806; J. Beckenkamp, 4.12 to 4.17; J. Samojloff, 4.21; and M. von Schwarz, 4.1 to 4.3. C. Doelter found the artificial crystals to have the sp. gr. 4.196; and R. Schneider, 3.6 at 15° ; while C. L. Burdick and J. H. Ellis calculated from the space-lattice values, Fig. 625, 4.24. E. H. Kraus and J. P. Goldsberry gave 4.2 for the sp. gr., 43.705 for the mol. vol., and for the topic axial ratios $\chi : \psi : \omega = 3.5407 : 3.5407 : 3.4897$. W. H. Goodchild studied the mol. vol., and J. J. Saslawsky calculated the vol. contraction which occurs in the formation of chalcopyrite. The hardness of chalcopyrite is 3.5 to 4.0; C. Doelter gave for the artificial crystals, 3 to 4. O. Mügge, and M. J. Buerger studied the plastic deformation of chalcopyrite. E. Madelung and R. Fuchs gave for the compressibility 0.05128 megabars per sq. cm. F. E. Neumann gave 0.1297 to 0.1282 for the sp. heat of chalcopyrite; P. E. W. Oeberg, 0.1291 between 14° and 99° ; J. Joly, 0.12708 to 0.12717 between 12° and 100° ; and A. Sella, 0.1278. J. Joly gave 470° for the m.p., whatever that may mean. L. H. Borgström gave 620° for the dissociation temp. A. de Gramont examined the spark spectrum; A. Pochettino, the cathodoluminescence; and G. Greenwood and D. Tombouljan,

the piezoelectricity. F. Beijerinck, and R. G. Harvey said that the electric conductivity of chalcopyrite is good, and changes with temp; H. Löwy gave 5×10^{13} c.g.s. units. A. Abt measured the electrical resistance of chalcopyrite; and T. W. Case observed no change in the resistance on exposure to light. For the observations of W. G. Hankel, E. Becquerel, R. Bunsen, A. Abt, and J. Stefan on the thermoelectric properties—*vide infra*, pyrite. W. Skey observed that in a soln. of sodium chloride, chalcopyrite is electronegative to silver. I. Bernfeld found that if used as anode in an acid soln., the copper passes into soln. and the sulphur remains behind, or, if the current density is high, it is oxidized. In alkaline soln., as anode, cupric hydroxide is formed and the sulphur is oxidized, and when used as cathode, a copper slime remains behind. E. F. Smith noted that the sulphur is oxidized if the powdered mineral be electrolyzed in molten potassium hydroxide with a nickel dish as anode. K. Fischbeck studied the electrolytic reduction of CuFeS_2 . E. T. Wherry found that chalcopyrite is a fair radiodetector; this subject was also discussed by C. Tissot and F. Pellin, H. S. Roberts and L. H. Adams, and W. Ogawa. W. Ogawa studied the thermoelectric properties of chalcopyrite and a current of $10,500\mu$ volt flows from the mineral to the copper at the hot junction. W. R. Crane gave 127×10^{-6} for the magnetic susceptibility.

According to P. Berthier, and C. F. Rammelsberg, when chalcopyrite is heated out of contact with air, about a quarter of the sulphur is given off: $2\text{CuFeS}_2 = \text{Cu}_2\text{S} + 2\text{FeS} + \text{S}$. According to F. Beijerinck, when chalcopyrite is heated out of contact with air, sulphur is given off, and, added F. Frölich, the mineral becomes more soluble in dil. acids. F. Thomas said that for the complete removal of the sulphur, the presence of some gangue minerals are necessary, and M. de K. Thompson, that the copper passes into cupric oxide. A. Mourlot found that about 10 per cent. sulphur remained after the mineral had been heated ten minutes in the electric arc furnace. R. Schneider found that at dull redness, 12.5 per cent. of sulphur is lost in an atm. of carbon dioxide, and 25 per cent. in an atm. of hydrogen.

The tarnishing of the mineral on exposure to air has been indicated above. The transformation of chalcopyrite into malachite and azurite where the mineral is exposed to carbonated waters, and also its transformation into chalcocite, Cu_2S , and covellite, CuS , have been frequently observed. The oxidation of chalcopyrite was studied by S. H. Emmens, H. Saito, W. H. Emmons, C. R. van Hise, R. C. Wells, and V. H. Gottschalk and H. A. Buehler—*vide infra*, iron pyrites. In nature there are various reactions associated with the action of cupric salt soln., say cupric sulphate, formed by the oxidation of ores in the upper levels; and various copper minerals are convertible one into the other. In illustration, E. G. Zies and co-workers found that by the action of soln. of cupric sulphate, heated in sealed tubes, chalcopyrite was converted into covellite and then to chalcocite; and P. von Jereméeff observed at a locality in the Altai Mts., every stage of transition from chalcopyrite to chalcocite. K. Schlossmacher observed the transformation of bornite into chalcopyrite; and H. A. Miers, and M. Brinkmann, the reverse change: $\text{Cu}_3\text{FeS}_3 + \text{Fe}_2\text{S}_3 = 3\text{CuFeS}_2$; E. Döll reported pseudomorphs of pyrite after chalcopyrite; T. Wada, of copper after chalcopyrite; and F. A. Genth, of hisingerite after chalcopyrite. J. W. Mellor found that when the powdered (200's lawn) mineral is heated, while a current of air is passed over the surface, the percentage losses of the contained sulphur when the mineral is heated 2 to 3 hrs. at the given temp., are those indicated in Fig. 626. F. Foreman observed that when chalcopyrite is heated in a sealed tube:

FIG. 626.—Loss of Sulphur when the Minerals are Heated in a Current of Air.

H. Freundlich and co-workers studied the adsorption of water. C. A. Burghardt found that when chalcopyrite is fused with ammonium nitrate, reddish-brown ferric oxide is formed. S. W. Parr found that the sulphur is all oxidized by the action of molten sodium dioxide; J. Matuschek, by fused potassium nitrate; and C. Boucher, by a mixture of sodium persulphate and ammonium nitrate. R. Schneider said that it is not attacked by hot or cold water. According to C. Doelter, water alone dissolves 0.1660 per cent. of the iron in the chalcopyrite employed. J. Lemberg found that alkaline bromine-water colours the mineral bronze-brown and forms copper and ferric oxides. E. Schäfer said that the mineral is slowly attacked by chlorine at ordinary temp., but at a higher temp. the action is quicker; bromine acts more slowly than chlorine. H. N. Stokes observed that chalcopyrite when exposed to bromine vapour for half a minute, and then to hydrogen sulphide gas, is blackened, whereas iron sulphides remain bright. R. Schneider found that dil. hydrochloric acid has no action, but the hot, conc. acid attacks it vigorously without all the iron passing into soln. A. Knop observed that hydrochloric acid extracts the iron as oxide leaving behind most of the copper—no hydrogen is given off. According to F. Beijerinck, hydrochloric acid slowly attacks chalcopyrite forming covellite. E. E. and I. W. Wark observed the effect of sulpho-compounds on the flotation of the mineral. E. F. Smith said that chalcopyrite is decomposed by sulphur monochloride at 140°, and S. W. Young and N. P. Moore showed the action of soln. of alkali sulphides to be very small. A. Himmelbauer observed the corrosion figures with warm sodium hydroxide soln., and J. Lemberg observed that the boiling lye makes the surfaces of the crystals matt. T. T. Read found that sulphurous acid extracts the iron as ferrous sulphate. A. Himmelbauer did not obtain corrosion figures with sulphuric acid, but Z. Toborffy did. S. W. Young and N. P. Moore observed that a soln. of 0.1N-H₂SO₄ along with hydrogen sulphide, becomes turbid. R. Schneider found that the mineral is not attacked by dil. alkali lye, or by dil. aq. ammonia. He also found that cold nitric acid of sp. gr. 1.2 has no action, but the mineral dissolves in the hot acid, forming a green soln. with the separation of sulphur; and Z. Toborffy studied the corrosion figures obtained with nitric acid. Aqua regia is the best solvent for chalcopyrite. E. Wilke-Dörfurt and E. A. Wolf opened the mineral for analysis by heating it in the vapour of iodine trichloride. O. Gasparini found that the mineral is energetically oxidized in the presence of nitric acid undergoing electrolysis. J. Lemberg observed that chalcopyrite is not soluble in a boiling soln. of potassium cyanide; he also showed that a soln. of potassium ferrocyanide in acetic acid gradually forms a film of brown copper ferrocyanide which later changes into prussian blue. K. B. Rogers showed that the heated mineral is decomposed by the vapour of carbon tetrachloride. W. O. Hickok observed that chalcopyrite is not acted on by a soln. of stannous chloride. H. N. Stokes found that when a mineral is treated with a soln. of ferric sulphate—*vide infra*, pyrite—bornite can be distinguished from chalcopyrite even when the proportion of copper is less than 3 per cent. A sulphuric acid soln. of silver sulphate at 50°, is coloured reddish-violet by chalcopyrite. Nascent hydrogen from zinc and sulphuric acid was found by F. Beijerinck to develop hydrogen sulphide; if the point of an electrode in an electrolytic current is placed on a polished section of chalcopyrite, a black film appears whilst pyrite and pyrrothite do not change their appearance. F. P. Treadwell found that if the mineral is heated to dull redness with *ferrum reductum*, in an atm.

of carbon dioxide, ferrous sulphide is formed. T. T. Read observed that if placed in a soln. of copper sulphate, the chalcopyrite becomes richer in copper sulphide. F. Thomas observed that a soln. of ferric sulphate decomposes the mineral slowly, and if powdered rapidly, as observed by F. Thomas, and M. de K. Thompson, the decomposition is faster after an oxidizing roast at 450° – 480° . J. B. Cammerer showed that a soln. of 4 mols of ferric chloride when heated with a mol of finely-powdered chalcopyrite, yields 5 mols of ferrous chloride, a mol of cupric chloride, and 2 gram-atoms of sulphur. F. W. Schmidt found that chalcopyrite is decomposed by an ammoniacal soln. of mercuric cyanide; and P. V. Gladkoff, that chalcopyrite rapidly precipitates gold from a dil. soln. of gold chloride. A. K. Burn discussed the flotation of the ore in sea-water, and A. M. Gaudin and W. D. Wilkinson, flotation in the presence of dioxanthogen.

The mineral **barnhardite** was found by F. A. Genth⁷ on D. Barnhardt's land, Cabarrus Co., North Carolina, and it has been reported from a few other localities. Analyses presented by F. A. Genth, N. S. Higgins, and F. von Dieffenbach agree approximately with **cuprous ferric pentasulphide**, $\text{Cu}_4\text{Fe}_2\text{S}_5$, or $2\text{Cu}_2\text{S} \cdot \text{Fe}_2\text{S}_3$. The mineral occurs in bronze-yellow compact masses. It tarnishes easily on exposure to air. Its sp. gr. is 4.521, and its hardness 3.5. E. H. Kraus and J. P. Goldsberry gave 4.521 for the sp. gr.; 38.806 for the mol. vol., and for the topic axial ratios $\chi : \psi : \omega = 3.3856 : 3.3856 : 3.3856$. It may be chalcopyrite partly altered to chalcocite. **Cuprous ferrous stannic sulphide**, $\text{Cu}_2\text{S} \cdot \text{FeS} \cdot \text{SnS}_2$, was discussed in connection with tin—7. 76, 24.

In 1725, J. F. Henckel⁸ referred to a mineral which he called *Kupfer-lazul*; J. G. Wallerius applied several terms to the brown or violet copper ore, or *cuprum sulfure et ferro mineralisatum*; A. Cronstedt called it *Koppar-lazur* or *miner acupri lazurea*; A. G. Werner, *Buntkupfererz*; R. Kirwan, *purple copper ore*; and R. J. Haüy, *cuvre pyriteux hépatique*. Several other names have been proposed; F. S. Beudant, *phillipsite*—after W. Phillips—but the term was already in use for an aluminosilicate; E. F. Glocker, *poikilopyrite*—from *ποικίλος*, variegated; A. Breithaupt, *poikilite*, and also *Buntkupferkies*; W. Haidinger, *bornite*—after I. Eques a Born; J. D. Dana, *erubescite*—from *erubescere*, to redden; and C. W. Blomstrand, *chalcomiklite*.

A massive mineral resembling bornite was described by C. F. Rammelsberg.⁹ It came from Guanasevi, Mexico; its sp. gr. ranged from 5.19 to 5.24, and its hardness was 3. The mineral was called *castillite*, and its composition was represented by the formula $(\text{Cu}, \text{Ag})_2\text{S} \cdot 2(\text{Cu}, \text{Pb}, \text{Au}, \text{Fe})\text{S}$, but, as emphasized by J. D. Dana, and G. Kalb, it is probably an impure bornite. R. Pearce observed a related mineral in Butte, Montana.

Analyses were reported by the early workers, M. H. Klaproth,¹⁰ W. Hisinger, R. Brandes, J. J. Berzelius, C. F. Plattner, P. Berthier, C. Staaf, A. Chodneff, W. and R. Phillips, C. Bergemann, and T. Bodemann; and by the later workers, C. F. Rammelsberg, F. Sandberger, F. Katzer, L. Mrazek, G. A. Kenngott, C. Mène, L. L. de Koninck, W. I. Macadam, P. T. Cleve, D. Forbes, I. Domeyko, M. Böcking, A. Hilger and E. von Gerichten, E. von Bibra, B. J. Harrington, A. d'Achiardi, J. D. Dana, H. F. Collins, E. H. Kraus and J. P. Goldsberry, etc. J. J. Berzelius, W. Hisinger, and W. and R. Phillips concluded from their analyses that the mineral is a complex of $2\text{Cu}_2\text{S} \cdot \text{FeS}$; while C. F. Plattner regarded it as a complex **cuprous ferric trisulphide**, $3\text{Cu}_2\text{S} \cdot \text{Fe}_2\text{S}_3$, i.e. Cu_3FeS_3 , which C. F. Rammelsberg represented by $\text{Cu}_2\text{S} \cdot \text{CuS} \cdot \text{FeS}$. Actually, as emphasized by C. F. Rammelsberg, the analyses extend over a considerable range—the copper being 45 to 70 per cent., and the iron, 6.5 to 15 per cent. As F. von Schaffgotsch showed, quite a number of different formulæ might be defended as giving the best representative value ranging from $\text{Cu}_2\text{S} : \text{Fe}_2\text{S}_3 = 3 : 1$ to $9 : 1$. G. Nordenström, C. F. Rammelsberg, and P. Groth favoured $3\text{Cu}_2\text{S} \cdot \text{Fe}_2\text{S}_3$; and P. T. Cleve, E. T. Allen, and B. J. Harrington, $5\text{Cu}_2\text{S} \cdot \text{Fe}_2\text{S}_3$; and E. H. Kraus and J. P. Goldsberry gave formulæ $\text{Cu}_6\text{Fe}_2\text{S}_6$, $\text{Cu}_8\text{Fe}_2\text{S}_7$, etc., up to $\text{Cu}_{76}\text{Fe}_2\text{S}_{41}$, where the minerals are represented by the general formula: $\text{Cu}_n\text{Fe}_2\text{S}_{\frac{n}{2}+3}$. H. Baumhauer proved by microscopic observations that

the bornite is particularly liable to contain admixtures—principally chalcocite. J. C. Ray showed that bornite is relatively unstable and readily passes into chalcocite and chalcopyrite with water in sealed bombs at 100° to 175° . A. F. Rogers suggested that the variation in other cases is due to the existence of solid soln. of Cu_2S in CuFeS_2 .

The discussion on the formation of chalcopyrite in nature applies to a large extent to bornite, for both minerals are primary constituents from which many other copper minerals are derived. Both minerals indeed frequently occur together. The observations of B. Lotti, R. Beck and W. von Fircks, A. Schenck, J. F. Kemp, S. G. Lasky, W. H. Weed, J. Catharinet, H. W. Turner and A. F. Rogers, and P. von Jereméeff on the occurrence of chalcopyrite in serpentized, dioritic, and pegmatitic rocks apply also to bornite, and agree with the assumption that bornite is of magmatic origin. The occurrence of bornite has been also discussed by A. Frenzel, W. Lindgren, C. Klein, A. F. Rogers, H. Schneiderhöhn, R. H. Sales, E. Weinschenk, P. Geijer, C. Baret, F. B. Laney, P. Krusch, F. Beyschlag, T. L. Walker, K. Schlossmacher, and R. M. Overbeck. Pseudomorphs of bornite after chalcocite and chalcopyrite have been observed, and discussed by C. C. von Leonhard, F. P. Mennel, and K. Schlossmacher. G. Gilbert discussed what he called the antipathy of bornite for pyrrhotite, because he believed that the minerals are mutually exclusive, and if a specimen of one mineral is found, the other will be absent.

A. Reuss observed crystals of bornite in the masonry of a blast-furnace at Trautenau, Bohemia; F. N. Guild, in cavities in the masonry of a smelter at Miami, Arizona; and A. N. Winchell, in a furnace at Butte, Montana. A. Lacroix, and A. Daubrée observed crystals of bornite occur on Roman bronze coins and bronzes which were exposed to the waters of the thermal springs at Bourbonne-les-Bains.

M. Böcking obtained a product resembling bornite by melting, under a layer of sodium chloride, a mixture of 36 grms. of copper, 10 grms. of iron, and sulphur; and F. Marigny, under a layer of borax, a mixture of 20 parts of pyrites, 45 parts of copper, and 20 parts of sulphur. C. Doelter obtained bornite by heating a mixture of different proportions of cuprous, cupric, and ferric oxides in hydrogen sulphide at 100° to 200° . He thus obtained cubic crystals of Cu_3FeS_3 , and with other mixtures, products like $\text{Cu}_9\text{Fe}_4\text{S}_{10}$, and $\text{Cu}_4\text{Fe}_3\text{S}_7$. E. G. Zies and co-workers found pyrrhotite passes into chalcopyrite and probably bornite when it is heated in a sealed tube with a soln. of copper sulphate.

The colour of bornite ranges between copper-red and pinchbeck-brown on a freshly-fractured surface, but the surface quickly tarnishes and appears iridescent.

• = S; ○ = Cu; ⊙ = Cu; ⊗ = Fe
— = twofold axis

FIG. 627.—The Unit Cubic Cell of Bornite.

Some of the names proposed for the mineral refer to the lustre of the tarnish; and other names, like *peacock ore*, and *horse-flesh ore*, are miners' names suggested by the colour of the mineral. The streak is pale grayish-black, and J. L. C. Schroeder van der Kolk found that the colour of the streak or powder varies with different specimens. Bornite may occur massive with a granular or compact structure; and, as shown by C. C. von Leonhard, and W. Phillips, it occurs in cubic crystals whose habit may be cubic with the faces rough or curved. F. Mohs suggested that the crystals are rhombohedral with an angle of 95° , but W. Haidinger showed that the crystals are really cubic, and he compared the effects of twinning of bornite

with that of fluorite. The crystals were also described by A. Breithaupt, L. Buchrucker, A. Lévy, J. D. Dana, etc. Twinning may occur about the (111)-plane, and there may be penetration twinning hexagonal in form. There are traces

of cleavage on the (111)-face. P. F. Kerr, and W. de Jong made observations on the **X-radiogram** of bornite, Cu_5FeS_4 . The unit cubic cell is illustrated by Fig. 627. According to J. W. Gruner's summary, of the 40 copper atoms in the unit cell, 32 are cuprous and 8 are cupric. The 32 sulphur atoms occupy the position of oxygen in magnetite, and form a tetrahedral network of face-centred, close-packed particles. The 32 cuprous atoms are arranged in the same manner, and their tetrahedra bear the same relationship to those of the S-atoms, that a positive tetrahedron does to a negative one. There is a small, negligible discrepancy of less than 3 per cent. of the parameter of the cuprous atom. The structure of these 64 atoms closely resembles that of PbS (sodium chloride type). The eight cupric atoms, and eight ferrous atoms are placed in the centres of some of the tetrahedra of sulphur and cuprous atoms. The variable composition of bornite between $\text{Cu}_8\text{Fe}_2\text{S}_8$ and $\text{Cu}_{18}\text{Fe}_2\text{S}_{12}$ is the result of an isomorphous replacement of ferrous by cupric atoms and *vice versa*. These two types of atoms have very similar positions, being comparable with positive and negative tetrahedra. Partial replacement should therefore be common. H. Schneiderhöhn studied the microstructure of polished surfaces; J. W. Gruner, intergrowths with chalcopyrite and chalcocite; P. Geijer, corrosion figures with nitric and hydrochloric acids, and soln. of potassium cyanide, and W. Fackert used the corrosive liquid recommended above for chalcopyrite. G. M. Schwartz studied intergrowths with chalcocite.

F. Sandberger gave 5.7 for the sp. gr.; F. Katzer, 4.91; C. Staaf, 4.988; P. T. Cleve, 4.81 to 5.425; C. F. Rammelsberg, 5.03; and E. T. Allen, 5.037 to 5.103 at 25°/25°. The sp. gr., of course, varies with the composition. E. H. Kraus and J. P. Goldsberry gave for the sp. gr. the mol. vol.:

	$\text{Cu}_8\text{Fe}_2\text{S}_8$	$\text{Cu}_{10}\text{Fe}_2\text{S}_8$	$\text{Cu}_{12}\text{Fe}_2\text{S}_9$	$\text{Cu}_{12}\text{Fe}_2\text{S}_{10}$
Sp. gr.	4.9	5.072	5.086	5.248
Mol. vol.	34.977	32.989	32.672	31.516

The topic axial ratios $\chi : \psi : \omega$ were all 3.2704 for $\text{Cu}_8\text{Fe}_2\text{S}_8$; 3.2072, for $\text{Cu}_{10}\text{Fe}_2\text{S}_8$; 3.1950 for $\text{Cu}_{12}\text{Fe}_2\text{S}_9$; and 3.1587 for $\text{Cu}_{14}\text{Fe}_2\text{S}_{10}$. J. J. Saslawsky calculated the contraction which occurs in the formation of bornite. The hardness of the mineral is 3. A. Sella found the sp. ht. to be 0.1195. J. Joly gave 430° for the m.p., whatever that may mean. A. de Gramont examined the spark spectrum. R. D. Harvey, and F. Beijerinck showed that the electric conductivity of the mineral is good, and increases with rise of temp.; and T. W. Case observed no change in the resistance on exposure to light. E. T. Wherry found that bornite is a poor radio-detector; H. S. Roberts and L. H. Adams discussed the use of bornite as a radio-detector, and W. Ogawa found that the thermoelectric force of bornite against copper is 6650 μ volt, and the current flows from copper to the mineral at the hot junction.

J. F. L. Hausmann found that while bornite is readily oxidized in moist air, it is not oxidized in dry air. J. W. Mellor's observations on the oxidation of the powdered mineral in a limited supply of air are indicated in Fig. 626. Bornite oxidizes faster than chalcopyrite. F. Carmichael observed that 0.01 per cent. of powdered bornite is oxidized when the powdered mineral is agitated for 13 days with water and oxygen. S. H. Emmens, W. H. Emmons, R. C. Wells, C. R. van Hise, and V. H. Gottschalk and H. A. Buehler studied this subject—*vide infra*, iron pyrites. R. Blanchard and P. F. Boswell discussed the formation of limonite from bornite. J. Lemberg observed that with alkaline bromine-water, bornite acquires a brownish-black film of copper and ferric oxides. J. Lemberg found that bornite is soluble in conc. hydrochloric or nitric acid with the separation of sulphur, and in a boiling soln. of potassium cyanide—pyrite, chalcopyrite, magnetite, and löllingite are not soluble in that menstruum. E. E. and I. W. Wark studied the effect of sulpho-compounds on the flotation of the mineral. S. W. Young and N. P. Moore found that bornite is stable in a 0.1N- H_2SO_4 sat. with hydrogen sulphide; and with an alkaline soln. of potassium sulphide, or water sat. with hydrogen sulphide, bornite is peptized, and the colloidal soln. forms chalcocite, and chalc-

pyrite. J. D. Sullivan found that bornite is soluble in soln. of ferric sulphate. J. Lemberg said that with potassium ferrocyanide and hydrochloric acid, brown copper ferrocyanide and prussian blue are formed—*vide supra*, chalcopyrite.

C. F. Rammelsberg¹¹ applied the term *cupropyrrite* to a mixture of chalcopyrite and pyrite; it had the general properties of cubanite—*vide infra*—but differed from it in chemical composition and sp. gr. C. H. Scheidhauer represented it by the formula: CuFe_2S_3 , or $\text{Cu}_2\text{Fe}_4\text{S}_6$, and proposed to call it **barracanite** in allusion to its occurrence at Barracanao, Cuba. Analyses were reported by C. H. Scheidhauer, and J. D. Dana. P. Groth and K. Mieleitner considered it to be **cupric ferric disulphide**, $\text{Cu}(\text{FeS}_2)_2$. The crystals belong to the cubic system; and the sp. gr. given by J. D. Dana is 4.17 to 4.18.

A. Breithaupt applied the term *cuban*, and E. J. Chapman **cubanite** to a bronze- or brass-yellow, massive mineral from Barracanao, Cuba. Analyses reported by C. H. Scheidhauer, P. T. Cleve, and R. Schneider correspond with **cuprous ferric hexasulphide**, $\text{Cu}_2\text{Fe}_4\text{S}_6$, or $\text{Cu}_2\text{S} \cdot \text{Fe}_4\text{S}_5$, or $\text{Cu}_2\text{S} \cdot \text{FeS}_2 \cdot 3\text{FeS}$. C. F. Rammelsberg, and G. A. Kenngott regarded cubanite as a variety of bornite with a high proportion of iron sulphide. R. Schneider gave the formula CuFeS_4 for cubanite. C. F. Rammelsberg based his formula on the reaction between cubanite and silver nitrate which is symbolized: $\text{Cu}_2\text{S} \cdot 3\text{FeS} \cdot \text{FeS}_2 + 10\text{AgNO}_3 = 4\text{Ag}_2\text{S} \cdot \text{FeS}_2 + 2\text{Cu}(\text{NO}_3)_2 + 3\text{Fe}(\text{NO}_3)_2 + 2\text{Ag}$. The crystals belong to the cubic system; and the sp. gr. is 4.026 to 4.042, and the hardness 3.5. H. E. Merwin and co-workers argued that cubanite and chalmersite are really the same minerals, both rhombic; and P. Geijer, that cubanite and chalcopyrite are the same. J. W. Gruner, G. W. Schwarz, P. Ramdohr, A. Bibolino, N. W. and M. J. Buerger, and W. H. Newhouse discussed intergrowths with chalcopyrite.

E. Hussak¹² described a brass- or bronze-yellow mineral from Minas Geraes, Brazil, which was called **chalmersite**—after G. Chalmers. According to C. Palache, analyses reported by G. Kalb and M. Bendig, and E. T. Allen, corresponded with $\text{Cu}_2\text{S} \cdot \text{Fe}_4\text{S}_5$, or CuFe_2S_3 , whilst E. Hussak gave CuFe_2S_4 , or $\text{Cu}_2\text{S} \cdot \text{Fe}_4\text{S}_7$. P. Groth and K. Mieleitner regarded chalmersite as a sulphosalt, $\text{FeCu}(\text{FeS}_3)$. The rhombic crystals were found by C. Palache to have the axial ratios $a : b : c = 0.5725 : 1 : 0.9637$; C. Hlawatsch gave 0.5822 : 1 : 0.5611; and E. Hussak, 0.5734 : 1 : 0.9649. The thin, elongated prisms have their vertical faces strongly striated, and the crystals are rarely tabular, parallel to (010). Twinning about the twinning plane (110) are common, and there are also contact and penetration twins probably about the plane (112). H. Schneiderhöhn discussed the microstructure. F. Rinne showed that the crystals are isomorphous with those of chalcocite; there is a marked resemblance between the crystals of chalmersite and pyrrhotite. E. Thomson, G. Kalb and M. Bendig, and H. E. Merwin and co-workers emphasized the identity of chalmersite and cubanite. The sp. gr. of chalmersite is 4.04 to 4.68; its hardness 3.5; and its m.p. 910° to 920° . H. E. Merwin and co-workers add that chalmersite is unique in having only one axis, the *a*-axis, of high magnetic susceptibility; the susceptibilities of the *b*- and *c*-axes are feeble. E. Hussak, E. T. Allen, and H. Schneiderhöhn discussed the paragenesis of the mineral.

C. W. Blomstrand¹³ described a massive mineral resembling pyrite with a tinge of brown, occurring at Nya Kopparberg, Sweden; he called it **chalcopyrrhotite**, or rather *chalcopyrrhotin*. The analysis corresponds with CuFe_4S_6 ; C. W. Blomstrand gave **cupric ferrous ferric hexasulphide**, $\text{CuS} \cdot \text{Fe}_2\text{S}_3 \cdot 2\text{FeS}$; C. F. Rammelsberg, $\text{Cu}_2\text{S} \cdot 2\text{FeS} \cdot 4\text{Fe}_2\text{S}_3$; and P. Groth and K. Mieleitner, $(\text{Fe}, \text{Cu})_3(\text{FeS}_3)_2$. The sp. gr. is 4.28, and the hardness 3.5 to 4.0. The mineral **vallerite** from Kaveltorp, described by P. Ramdohr and O. Oedman, has the composition $\text{Cu}_2\text{Fe}_4\text{S}_7$.

R. Schneider¹⁴ prepared **potassium cuprous ferric tetrasulphide**, $2\text{K}_2\text{S} \cdot 3\text{Cu}_2\text{S} \cdot \text{Fe}_2\text{S}_3$, or $\text{K}_2\text{Cu}_3\text{FeS}_4$, by melting together powdered copper and iron with potassium carbonate and sulphur; likewise also with the corresponding **sodium cuprous ferric tetrasulphide**, $2\text{Na}_2\text{S} \cdot 3\text{Cu}_2\text{S} \cdot \text{Fe}_2\text{S}_3$, or $\text{Na}_2\text{Cu}_3\text{FeS}_4$. The salts form bronze-coloured rhombic plates, which, according to L. Cambi and L. Szegö, are really

solid soln. with a tetragonal lattice $a : c = 1 : 1.182$. R. Schneider found that by treating potassium ferric sulphide with silver nitrate, **silver ferric disulphide**, $\text{Ag}_2\text{S} \cdot \text{Fe}_2\text{S}_3$, or AgFeS_2 , is formed, and with sodium ferric sulphide, **silver ferric tetrasulphide**, $2\text{Ag}_2\text{S} \cdot \text{FeS}_2$, or Ag_4FeS_4 , is formed—*vide supra*, the sodium salt.

W. Haidinger¹⁵ observed at Joachimsthal, Bohemia, a mineral which he called **sternbergite**—after C. Sternberg. A. Breithaupt called it *silver pyrites*, and C. W. Blomstrand, *argyropyrrhotite*. Analyses, not very concordant, reported by F. H. M. Zippe, C. F. Rammelsberg, and C. Vrba, correspond, in the idealized case, with **silver ferrous trisulphide**, AgFe_2S_3 , or $\text{Ag}_2\text{S} \cdot \text{Fe}_4\text{S}_5$. W. S. von Waltershausen described another mineral from Joachimsthal, Bohemia, and he called it **argento-pyrite**. The analysis corresponded with **silver ferrous pentasulphide**, AgFe_3S_5 . G. Cesaro studied these compounds. A. Weisbach also found in the Erzgebirge a mineral which he called **argyropyrite**. The analysis corresponded with **silver ferrous henasulphide**, $\text{Ag}_3\text{Fe}_7\text{S}_{11}$. C. Vrba likewise reported a mineral which he called **frieseite**—after M. von Friese. The analyses corresponded with **silver ferrous octosulphide**, $\text{Ag}_2\text{Fe}_5\text{S}_8$. They all belong to the rhombic system, and C. Hintze represented their composition and axial ratios as follows :

	a	b	c
Sternbergite, AgFe_2S_3	0.5832	1	0.8391
Argyropyrrhotite, $\text{Ag}_3\text{Fe}_7\text{S}_{11}$	0.5800	1	0.3000
Frieseite, $\text{Ag}_2\text{Fe}_5\text{S}_8$	0.5970	1	0.7352
Argentopyrite, AgFe_3S_5	0.5812	1	0.2749

A. Weisbach represented sternbergite by $\text{Ag}_3\text{Fe}_6\text{S}_9$, argyropyrite by $\text{Ag}_3\text{Fe}_7\text{S}_{11}$, and argentopyrite, $\text{Ag}_3\text{Fe}_9\text{S}_{15}$; and all three minerals by the general formula $\text{Ag}_3\text{Fe}_{n+6}\text{S}_{2n+9}$, which he compared with the felspar formula $\text{Na}_n\text{Ca}_{1-n}\text{Al}_{2-n}\text{Si}_{2+n}\text{O}_8$, but G. Cesaro does not think there is anything in the comparison. A. Streng compared the formula calculated from the analyses of all the silver pyrites, and concluded that they can be represented as combinations of silver sulphide, *i.e.* *acanthite*, Ag_2S , with $p\text{Fe}_m\text{S}_n$, that is, solid soln. of acanthite with pyrrhotite, whilst sternbergite corresponds with the simple formula AgFe_2S_3 . C. F. Rammelsberg represented the silver pyrites as mixtures of $3\text{Ag}_2\text{S} \cdot \text{Fe}_2\text{S}_3$ with $3\text{FeS} \cdot \text{Fe}_2\text{S}_3$. G. Cesaro regarded the silver pyrites series as silver sulphoferrites of acids of the general formula $(n+2)\text{Fe}_2\text{S}_3 \cdot (2m-n-4)\text{H}_2\text{S}$, where the basicity is $p = (2m-n-4)/(n+2)$. For the poly-salt, argentopyrite, $p = \frac{1}{3}$, and it is symbolized $\text{Ag}_2\text{S} \cdot 3\text{Fe}_2\text{S}_3$; for the meta-salt, frieseite, $p = 1$, and it is symbolized $\text{Ag}_2\text{S} \cdot \text{FeS} \cdot 2\text{Fe}_2\text{S}_3$; for argyropyrite, $p = 1.4$, and it lies between the meta- and pyro-salt—the parent acid is supposed to be $\text{H}_7\text{Fe}_5\text{S}_{12}$; and sternbergite is the normal ortho-salt, $\text{Ag}_2\text{S} \cdot 2\text{FeS} \cdot \text{Fe}_2\text{S}_3$. He represented argentopyrite by the formula :

and to explain the excess of sulphur in some cases he assumed the existence of complex chains $-\text{S}-\text{S}-\text{S}=(\text{S}_2)_n$. Of course, constitutional formulæ have no particular meaning in cases like these, where the composition ranges between limits some distance apart. G. Cesaro later gave for silver pyrites, AgFe_2S_3 ; argyropyrrhotite, $\text{Ag}_3\text{Fe}_7\text{S}_{11}$; argentopyrite, $(\text{Ag}_{10}\text{Fe})(\text{Fe}_7\text{S}_{11})_4$; sternbergite, $\text{Ag}_4\text{Fe}_9\text{S}_{15}$ to $\text{Ag}_8\text{Fe}_{16}\text{S}_{23}$; and frieseite, $\text{Ag}_6\text{Fe}_{15}\text{S}_{23}$ to $\text{Ag}_8\text{Fe}_{21}\text{S}_{33}$. O. Luedecke suggested that the silver pyrites are *morphotrope Mischungen* of sternbergite and marcasite; whilst F. Zambonini regarded the *silver pyrites* as solid soln. of the rhombic sulpho-salt AgFe_2S_3 , with rhombic α -pyrrhotite, when the latter has more or less sulphur in solid soln. This seems one of the most plausible guesses as to the nature of sternbergite and pyrrhotite, and the hypothesis was supported by V. Nikitin.

Sternbergite occurs in implanted crystals forming rose-like or fan-like aggregates which are coloured pinchbeck-brown with a violet tarnish on some of the faces. The axial ratios of the rhombic crystals were found by W. Haidinger to be 0.5832 : 1 : 0.8391. Twinning occurs about the (110)-plane; and the crystals may

be tabular, parallel to (001). The (001)-faces may be striated parallel to the (001)/(301)-edge. The pyramids are striated parallel to the intersection with the (001)-face. The (001)-cleavage is perfect, and the thin laminae are flexible like tin-foil. The crystals were discussed by W. H. Miller, V. Goldschmidt, and J. D. Dana. W. Haidinger gave 4·215 for the sp. gr., and A. Breithaupt, 4·101; the hardness is 1·0 to 1·5, and the mineral, like graphite, leaves a trace on paper. F. Beijerinck found that the mineral is a good electrical conductor. C. Doelter synthesized sternbergite by warming a mixture of ferric oxide and silver chloride in a current of hydrogen chloride. The artificial crystals were cubic octahedra, so that the compound may be dimorphous.

Argyropyrite occurs in bronze-yellow crystals which, according to A. Weisbach, are rhombic with the axial ratios $a : b : c = 0·5731 : 1 : 0·2968$, or $0·5859 : 1 : 0·30176$. The sp. gr. is 4·1 to 4·2, and the hardness, 3 to 4. Argentopyrite was said by W. S. von Waltershausen to occur in steel-grey or tin-white, monoclinic, six-sided twin crystals with no cleavage; and G. Tschermak observed pseudomorphs in small hexagonal crystals; but A. Schrauf showed that the crystals of argentopyrite are really rhombic and are pseudohexagonal by repeated twinning. The axial ratios are $a : b : c = 0·5812 : 1 : 0·2749$, like sternbergite if the c -axis be multiplied by 3. The sp. gr. is 5·5 or more, and the hardness, 3 to 4. F. Beijerinck said that the mineral is a good electrical conductor. Frieseite occurs in thin, translucent, dark greenish-grey plates belonging to the rhombic system, and, according to C. Vrba, having the axial ratios $a : b : c = 0·5970 : 1 : 0·7352$. Twinning occurs about the (110)-plane. The tabular crystals are parallel to (001), and the (001)-faces are striated parallel to the (001)/(111)-edge. There may be feather-like striations on the twins. The (001)-cleavage is perfect, and the laminae are flexible. The sp. gr. is 4·212 to 4·220, and the hardness 1 to 2.

H. Malfatti¹⁶ prepared **calcium ferric sulphide**, $\text{Ca}(\text{FeS}_2)_2$, by treating mixtures of hydrated ferric oxide, and calcium hydroxide with hydrogen sulphide, and **barium ferric sulphide**, $\text{Ba}(\text{FeS}_2)_2$, in a similar way. J. Thugutt treated a mixture of hydrated ferric oxide and magnesium hydroxide with hydrogen sulphide, and obtained **magnesium ferric hydroxysulphide**, $(\text{Mg}(\text{OH})_2 \cdot \text{Fe}_2\text{S}_3 \cdot 2\text{H}_2\text{O})$. R. Schneider prepared **cadmium ferric disulphide**, $\text{CdS} \cdot \text{Fe}_2\text{S}_3$, and **cadmium ferrous sulphide**, $2\text{CdS} \cdot \text{FeS}$, by the methods employed for the silver salts.

§ 42. The Iron Sulphides—Iron Disulphide.

La pyrite est à l'industrie chimique ce que le pain est à l'alimentation de l'homme.—
P. TRUCHOT.

The term **pyrites**— $\pi\upsilon\rho$, fire—was employed by the ancients to denote a number of minerals which gave sparks when struck with a hammer. It was employed by Dioscorides, in his *De materia medica* (5. 89), and by Pliny, in his *Historia naturalis* (36. 30), at the beginning of our era, for copper and iron pyrites, as well as for *molaes* or mill-stones. Pliny's use of the term is analogous to the use of $\sigma\pi\upsilon\sigma$ by Theophrastus, in his *Περὶ λίθος* (19), written about 315 B.C. According to E. O. von Lippmann,¹ the *misy* of Dioscorides and Pliny, was probably a form of copper pyrites. According to G. Hoffmann, the Grecian word $\piυ\rho\rho\iota\tau\eta\varsigma$ is synonymous with the *marquashitha* of the Arabians, a term borrowed from the Aramæans, and employed by Aby Mansur Muwaffak, an Arabian writer of the tenth century. The term appeared later as *marcasite* for a variety of pyrite. Geber, in his *Summa perfectionis magisterii*, and other writings, employed the term *marcasite* for pyrites, and, still later, as pointed out by E. Darmstädter, it was applied by the pharmacutists of the Middle Ages to bismuth (*q.v.*). G. Agricola translated the term pyrites by *Kis*, and J. F. Henckel designated crystalline pyrites *marchasita*. G. Agricola appears to have regarded copper pyrites as a variety of iron pyrites. J. G. Wallerius classed different varieties of *sulphur ferro mineralisatum* as (i) *Kies*, or iron pyrites; (ii) *Marcasite*; (iii) *Wasserkies*. Analogous classifications were made by L. A. Emmerling, and A. Breithaupt. J. Hill called the globular form *pyrites*, the crystalline form *marcasite*, and the massive form *mundic*. The term

marcasite was used by the old writers for antimony and bismuth. The *white pyrites*, *Wasserkies*, or *pyrites fuscus lamellosus* of J. G. Wallerius, received various terms in allusion to its paler colour, and in allusion to cockscomb or spear-shaped crystals. J. B. L. Romé de l'Isle, and R. J. Haüy at first regarded it as an irregular variety of common pyrites, but later, he distinguished between the prismatic, rhombic, or white pyrites, and the ordinary form crystallizing in various modifications of the cube. The analyses of J. J. Berzelius, and C. Hatchett established the chemical identity of the two varieties, for both had a composition approaching FeS_2 , and accordingly R. J. Haüy spoke of the *la dimorphie de fer sulfuré*. W. Haidinger applied the term **marcasite** to the white or prismatic variety, and **pyrite** to the cubic form. Both varieties can be included in the general term pyrites—A. Breithaupt used the term marcasite in this general way.

The terms *Wasserkies* and *Lebererz* were applied by G. Agricola, A. Cronstedt, and J. F. L. Hausmann to the marcasite variety. A. Cronstedt translated it *pyrites aquosus*, which, as J. D. Dana said, has little applicability, but may have been used in allusion to the greater tendency of the mineral to become moist and to weather than is the case with pyrite. G. Agricola considers the term *Wasserkies* to be an early corruption of *Weisserkies*—white iron pyrites. The term was also used for easily decomposable pyrites and hence pyrrhotite was included. A. Breithaupt translated G. Agricola's *Lebererz* as *hepatopyrites*, and E. F. Glocker translated the *Wasserkies* as *hydropyrites*. The white copper ore of J. F. Henckel was called by A. G. Werner, L. A. Emmerling, and A. Breithaupt, *Weisskupfererz*, and the light colour was attributed to the presence of arsenic. It was thought by A. Breithaupt to have *chemisch gebundenes Wasser*, and to be a definite mineral species—which he called *hydropyrites*—but J. J. Berzelius, and J. F. L. Hausmann did not regard it as a mineralogical individual. A. Breithaupt used the term *lonchidite*—a diminutive form: $\lambda\omicron\gamma\chi\acute{\iota}\delta\iota\omicron\nu$ of $\lambda\omicron\gamma\chi\eta$, the head of a javelin—for a variety of marcasite, with about 5 per cent. of arsenic; also *kyrosite*—from $\kappa\acute{\upsilon}\rho\omega\sigma\iota\varsigma$, a confirmation—for another arsenical variety which J. J. Berzelius considered to be more probably a mixture of copper sulphide and arsenical pyrites; and F. Sandberger called another variety of marcasite with about 2.7 per cent. of arsenic, *metalonchidite*. A variety of pyrite from Ribadeo, Galicia, containing tin and zinc, was called by G. Schulz and A. Paillette, *ballesterosite*—after L. Ballesteros. S. L. Penfield showed that the *blueite*, and *whatonite* of S. H. Emmons, are nickeliferous varieties of pyrite.

Numerous analyses and descriptions of pyrite have been reported—e.g., by C. F. Rammelsberg,² M. Amelung, C. von Hauer, G. A. Kenngott, J. F. Williams, C. Mène, A. d'Achiardi, F. A. Genth, E. C. Schiffer, V. Pöschl, E. G. de Angelis d'Ossat, A. Piutti and E. Stoppani, C. von John and C. F. Eichleiter, E. H. Kraus and J. D. Scott, J. Samojloff, E. T. Allen and co-workers, A. Liffa, E. Arbeiter, K. Bornemann and O. Hengstenberg, F. Kolbeck, H. Laspeyres, S. L. Penfield, W. Vernadsky, T. L. Walker, H. H. Knox, J. H. L. Vogt, C. Doelter, E. Weinschenk, A. Girard and H. Morin, G. Lunge, A. Voelcker, A. Eschka, M. Watanabe and W. R. Landwehr, G. H. Thiel, etc. The results are well summarized by the formula FeS_2 . Samples containing some nickel, $(\text{Fe}, \text{Ni}, \text{Co})\text{S}_2$, were reported by W. H. Emmons, S. L. Penfield, F. Kolbeck, and H. Laspeyres; cobalt, by H. Laspeyres, F. Kolbeck, W. Vernadsky, and E. Ebermayer. The presence of gold, and silver in pyrite was discussed by A. Schmidt, F. Behrend, E. Nowak, H. Bücking, J. Samojloff, A. Kromayer, W. Mietzschke, and G. H. F. Ulrich. W. N. Hartley and H. Ramage found sodium, potassium, copper, silver, and calcium in all the samples they examined, and gallium, indium, thallium, lead, manganese, and nickel in some of them. L. Lukacs found calcium, gold, mercury, arsenic and antimony in a number of samples. H. N. Stokes, and many others have discussed cupriferous pyrites; L. C. Marquart reported up to 5 per cent. of thallium in some pyrites—*vide* 5.36, 1. C. U. Shepard applied the term *teluspyrine* to a telluriferous pyrite from Sunshine Camp, Colorado; W. N. Hartley and H. Ramage, and others have noted the presence of selenium in pyrites. G. Schulz and A. Paillette found zinc and tin in some pyrites. Arsenical pyrite, and manganiferous pyrite were discussed by W. Vernadsky. W. N. Hartley and H. Ramage found platinum in some varieties.

Many investigators have assumed that pyrite contains both ferrous and ferric iron, and that the molecule is accordingly complex. N. S. Kurnakoff and co-workers assumed that the marked contraction which occurs in the formation of pyrite from its elements, as well as the great hardness of pyrite agree with the assumption that the molecule is highly polymerized $(\text{FeS}_2)_n$. P. Groth suggested that the molecule is doubled, $n=2$, and added that the iron is probably present in the ferrous state. E. Weinschenk, for instance, regarded this sulphide as a kind of magnetite and represented it by the formula $(\text{FeS}_2)_3$, in which one-third of the iron is ferrous, and two-thirds, ferric. This is supposed to be supported by C. F. Rammelsberg's observations:

W. B. Brown's formula

E. Weinschenk's formula

on the formation of pyrite by heating magnetite in an atm. of hydrogen sulphide. A. P. Brown's experiments indicated that while in marcasite all the iron is in the ferrous state, in pyrite, one-fifth is in the ferrous state, and four-fifths in the ferric state. He therefore gave $4\text{Fe}'''\text{S}_2$ (*vide supra*) for the formula of pyrite, and $\text{Fe}''\text{S}_2$ for marcasite. H. N. Stokes could find no difference in the relative proportions of ferrous and ferric iron in marcasite and pyrite—*vide infra*, pyrite. E. Weinschenk said that the formula, $\text{S}=\text{Fe}-\text{S}-\text{S}-\text{Fe}=\text{S}$, which assumes all the iron in pyrite to be ferric, is not probable because of the easy reducibility of the ferric sulphide; H. N. Stokes based a similar conclusion on the fact that ferric oxide is formed by the action of zinc carbonate in an alkaline soln., and in the absence of an oxidizing agent, on pyrite and marcasite, and he suggested that these minerals should be formulated $\text{Fe}_2\text{S}_3(\text{S})$. It will be remembered that in deducing conclusions from reactions of this type, it is assumed that during the reaction there is no essential change in the arrangement of the atoms of the iron compound when the sulphur atoms are displaced by oxygen. The different conclusions obtained by studying different reactions show that what elsewhere has been called the rule of the constancy of structural arrangement cannot be depended upon. J. Loczka showed a formula,

J. Loczka's formula

which assumes the iron to be all in the ferrous state, and is in agreement with the fact that on weathering, pyrite furnishes ferrous sulphate and sulphuric acid. This is in accord with the observations of P. Groth, C. Doelter, L. Benedek, E. T. Allen and co-workers, and G. W. Plummer; and with the X-radiograms observed by W. L. Bragg, A. Reis, M. L. Huggins, J. Beckenkamp, P. P. Ewald and W. Friedrich, and P. Niggli—*vide infra*, pyrites. L. C. Jackson also found that the magnetic properties of pyrite indicate that iron is present in the ferrous form. Pyrite may belong to a persulpho-salt analogous to the peroxy-salts typified by barium dioxide, BaO_2 . The constitution of pyrite with bivalent iron is then represented either by $\text{Fe}=\text{S}=\text{S}$ or by J. Loczka's formula (*vide supra*). The twinning of the sulphur atoms favours the assumption that iron pyrites is a ferrous disulphide, $\text{Fe}^{++}-\text{S}-\text{S}-$, containing a bivalent diatomic anion, as in the case of such peroxides as $\text{Na}^+\text{O}^{--}\text{O}-\text{Na}^+$; and of the mercurous ion Hg^+-Hg^+ in mercurous nitrate. The assumption is made by A. Werner that the iron is quadrivalent in pyrite, $\text{S}=\text{Fe}=\text{S}$; and this hypothesis is modified by P. Pfeiffer who assumed that pyrite has the complex radicles $[\text{Fe}(\text{S}_2)_6]$ and $[(\text{S}_2)\text{Fe}_6]$. E. Arbeiter studied the oxidation of pyrite by hydrogen dioxide, and concluded that one-fourth of the sulphur is differently oriented from the remaining three-fourths because it is more readily

oxidized. Consequently, in agreement with A. Beutell's formula for cobaltite, E. Arbeiter represented the constitution of pyrite :

E. Arbeiter's formula

Analyses of marcasite, made at the beginning of the nineteenth century, by C. Hatchett,³ and J. J. Berzelius showed that its ultimate composition is the same as that of pyrite, namely, FeS_2 . This was confirmed by the work of F. J. Malaguti and J. Durocher, A. Vogel and C. Reischauer, F. Sandberger, C. Trapp, C. F. Plattner, C. H. Scheidhauer, J. A. Antipoff, E. Arbeiter, E. T. Allen and co-workers, E. Ammermann, E. Manasse, F. Schöndorf and R. Schröder, G. Sirovich, A. Breithaupt, etc. M. J. Buerger concluded that the published analyses show that pure pyrite has the composition FeS_2 , and marcasite $\text{FeS}_{1.985}$. The proportion of arsenic was discussed by E. Arbeiter, and B. Kosmann—*vide* arsenopyrite, and löllingite; the nickel and cobalt, by B. Kosmann; and the thallium, by A. Breithaupt.

C. F. Rammelsberg regarded arsenical marcasite as a mixture of, say, 26FeS_2 and FeAs_2 ; and A. Beutell discussed this subject regarding FeS_2 and FeAs_2 as isomorphous, a subject discussed by J. W. Retgers, and A. Arzruni. W. B. Brown supposed that marcasite contained only ferrous iron, and should be represented :

W. P. Brown's formula

A. Beutell's formula

E. Arbeiter's formula

A. Beutell used the doubled formula just indicated, and it was favoured by P. Groth. E. Arbeiter showed that when oxidized with hydrogen dioxide, half the sulphur atoms behave differently from the other half in agreement with the assumption that they are differently oriented in the molecule as just indicated. F. Beijerinck favoured the ring formula; and M. L. Huggins gave a possible structure for the space-lattice—*vide infra*.

The history and composition of dimorphic **pyrites**, that is, **iron disulphide**, FeS_2 , as it appears in the form of cubic **pyrite** and rhombic **marcasite**, has been previously discussed in connection with the iron sulphides. G. Königsberger and O. Reichenheim⁴ believed that a third modification appears at 400° , but E. T. Allen and co-workers, and E. Arbeiter were unable to confirm the existence of forms of the disulphide other than marcasite and pyrite. As indicated below, there is a colloidal form of the disulphide. Pyrite occurs sparingly though frequently in rocks of all ages—from the oldest igneous rocks, to the later metamorphic rocks, and comparatively recent alluvial deposits; it was called by J. F. Henckel, in 1725, the *Jack-in-every-street-Pyrite*. It is commonly associated with magnetite or hæmatite, and in the neighbourhood of metallic veins, it may be accompanied by metal sulphide—*e.g.*, chalcopyrite, bornite, chalcocite, sphalerite, galena, etc. According to A. A. Julien, pyrite tends to predominate in the crystalline rocks largely constituted of magnesia- and iron-micas, hornblende, chlorite, and serpentine such as diorite, chlorite- and hornblende-schists, etc. It is prominent as well in weathered eruptive rocks and most granites, marbles, and clays; it occurs scattered in anthracite and nearly all metalliferous veins, and in clay beds. The pyritic deposits in nature have a widely different origin and history. (i) Some have crystallized directly from rock magmas, and were formed at a high temp., thus, J. H. L. Vogt found that the iron sulphides are soluble in silicate magmas at high temp., and that they are amongst the earliest minerals to crystallize from such magmas. (ii) Others are formed by contact metamorphism, and they may be connected with the eruption of igneous rocks although high temp. minerals are usually absent, and the gangue contains barite and calcite, as well as quartz—*e.g.*, the deposits of

Rio Tinto, Spain, discussed by J. H. Collins, A. M. Finlayson, F. Klockmann, L. de Launay, H. Preiswerk, J. Gonzalo y Tarin, J. H. L. Vogt, B. Wetzig, etc.; the deposits of Rammelsberg, Harz, Germany, discussed by F. Klockmann,⁵ J. H. L. Vogt, W. Lindgren and J. D. Irving, etc.; and the deposits of Mount Lyell, Tasmania, discussed by J. W. Gregory. (iii) Another class is generally thought to represent a phase of igneous injection for they have a close relation to the igneous rock formations—e.g., the Norwegian deposits at Vignas, Sulitelma, and Røros; the Swedish deposits at Fahlun and Bersbo; and the Bavarian deposit at Bodenmais. All these deposits may have been modified in structure and mineral association by dynamic metamorphism. W. A. Tarr noted sulphide inclusions in Joplin calcites, and also alternating deposits of pyrite and marcasite. Marcasite, said he, is deposited by acidic soln., pyrite by neutral or slightly acidic soln., and melnikovite by alkaline soln. The occurrence of pyrites is discussed by P. Truchot, *Les pyrites* (Paris, 1907), and by A. W. G. Wilson, *Pyrites in Canada* (Ottawa, 1912); and the paragenesis, by W. H. Newhouse.

Pyrite and other sulphides may be precipitated by chemical reactions in sediments, and thus appear in sedimentary formations—clays, shales, marls, limestone, coal, etc. In many cases, the pyrites is supposed to have been formed by the reduction of soln. of iron sulphate by organic matter. M. Longchamp⁶ observed iron pyrites as a deposit from the mineral water in a narrow channel of the thermal spring at Chaudesaigues; J. J. Noggerath found the limestone in the thermal springs of Aix-la-Chapelle was covered with a film of pyrites; and G. Bischof made analogous observations. He also found that water containing sulphates and organic matter was able to convert ferrous carbonate into pyritic crystals. A. Liveridge mentioned a case of the formation of pyrite on twigs in the hot spring at Tempo, New Zealand; and H. Kiefer, in the rocks of the Upper Rhine; J. L. G. Meinecke found the wood in a swamp at Dölau was incrustated with pyrites; L. W. Gilbert, and H. F. Link made similar observations. R. Bakewell showed that some mouse droppings accidentally kept in a flask in contact with a soln. of ferrous sulphate for some time, became covered with crystals of pyrites. Observations on the subject were made by G. Forchhammer, A. Daubrée, C. W. C. Fuchs, F. Fouqué and A. Michel-Lévy, and F. J. Malaguti and J. Durocher. A. Gautier discussed the formation of hydrogen sulphide by the decay of organic matter. According to M. W. Beyerinck, certain micro-organisms—bacteria, algae, infusoria, and flagellata—favour the formation of pyrites in surface soils by evolving hydrogen sulphide as a product of the reduction of sulphates. J. von Fodor said that micro-organisms in soils have been discovered only at a depth of about 5 metres. Observations on the formation of pyrites by the reduction of sulphates by swamp water, spring water, etc., were made by A. R. Whitman, C. O. Harvey, V. Rodt, C. Ochsenius, W. Feld, H. Schneiderhöhn, R. Brauns, A. Lacroix, H. Winter and G. Free, and E. Joukowsky. G. Sirovich did not favour the hypothesis that pyrites is formed, geologically, by the reduction of ferrous sulphate soln. by organic matter: $7C + 4FeSO_4 = 2FeCO_3 + 2FeS_2 + 5CO_2$; nor did E. T. Allen and co-workers obtain satisfactory results in the reduction of ferrous sulphate soln. by starch and glucose, even at temp. as high as 300°; but the frequent occurrence of pyrites on coal, and its occasional formation on wood, indicate that the reduction may occur.

According to E. T. Allen and co-workers, the sulphide produced by ascending waters is always pyrite, never marcasite, and such waters are naturally hot, and nearly always alkaline. A. Daubrée noted the formation of pyrite in the springs of Carlsbad where the temp. is about 55°. The deposition of pyrites by the Tuscan lagoons, was observed by J. Nöggerath and G. Bischof; R. Bunsen noted that the hot vapours of the fumaroles in Iceland are slowly converting the ferrous silicate of the rocks into pyrites; and A. Lacroix observed that pyrite and pyrrhotite were formed in the eruption of Vesuvius in April, 1906, owing to the action of hydrogen sulphide on the volatilized ferrous chloride. E. T. Allen and co-workers found that

both marcasite and pyrite can be formed by the agency of hydrogen sulphide under geological conditions; and added that pyrite, in the majority of cases, and marcasite, in all cases, crystallize from aq. soln. The pyrite of deep veins, metamorphic contacts, thermal springs, and magmas has been formed by *hot* soln., and these soln. never contain strong mineral acids, but are generally, if not always, alkaline. The pyrite and marcasite of surface veins, on the other hand, are formed from *cold* soln. which often contain a relatively high proportion of sulphuric acid.

J. R. Blum⁷ described pseudomorphs of pyrite after barytes; A. Breithaupt, after fluorite; G. vom Rath, after magnesite; K. Zimanyi, after calcite; G. Tschermak, after augite; E. Döll, after tourmaline, and epidote; and F. Schumacher, after biotite. Fossils also may consist of pyrites when the mineral has been formed by the reduction of soln. of ferrous sulphate by organic matter; and it may also explain the formation of nodules of pyrite and marcasite found in clays, and chalk beds. A. Gautier, for instance, showed that hydrogen sulphide is one of the products of the putrefaction of organic matter, and that the pyrite which forms the substance of some fossil bones and shells is precipitated by hydrogen sulphide given off by the decomposing organic matter. This subject was discussed by P. Fallot, and E. Joukowsky.

Unlike pyrite, marcasite does not occur as a primary constituent of magmas, because, as shown by E. T. Allen and co-workers,⁸ marcasite is unstable at temp. exceeding 450°—*vide infra*. Marcasite occurs only in sedimentary deposits, and metalliferous veins. It is formed in surface veins from cold acidic soln., and mixtures of pyrite and marcasite may have been formed at higher temp., up to, say, 300°, or in the presence of less acid, or both. The formation of pyrite is favoured by alkaline soln., and temp. exceeding 450°. G. V. Douglas, F. R. and K. R. Horn, V. R. von Zepharovich, T. Brandes, T. Scheerer, H. N. Stokes, W. S. T. Smith and C. E. Siebenthal, and E. T. Allen and co-workers observed marcasite and pyrite associated together in concentric layers, etc. C. Hintze mentions thirty-one cases where the two minerals have intergrown or been precipitated one on the other. As in the case of pyrite (*q.v.*), it may be formed by what appears to be the reduction of sulphate soln., as observed by E. F. Glocker. A. A. Julien said that marcasite is largely or wholly the pyrites of thin seams and coatings in coal-beds, lignitic shales, dolomites, limestones, and in general unaltered sedimentary rocks like sandstones, graywacke schists, peat, clay, bituminous coals, casts of fossils, and veins of galena. It occurs in stalactitic forms. E. Kalkowsky observed incrustations—*marcasite patina*—on some wooden piles. Spear-shaped crystals occur in the plastic clay of the brown coal formation of Littmitz, and Altsattell, Bohemia, where it was mined for its sulphur, and the manufacture of ferrous sulphate. C. Winkler described cryptocrystalline pyrites formed in the inside of cast-iron tubes conveying sulphide liquors in the manufacture of sodium carbonate; these crystals, according to C. Doelter, are marcasite. C. Reidemeister observed the crystals were formed in the joints of a plant used for the purification of sulphur. Pseudomorphs of marcasite after many minerals have been observed. H. Schneiderhöhn noted the following sequence: siderite→pyrrhotite→marcasite→pyrite; and E. Döll also noted pseudomorphs of pyrite after marcasite. J. F. L. Hausmann reported small crystals of pyrite in the sole of an old roasting furnace in the Harz. B. von Cotta also observed pyrites as a furnace product; and G. Lowe observed that in the sublimation, at a dull red-heat, of ammonium chloride containing some sulphate from an iron vessel filled with clay, cubes and octahedra of pyrites were formed on the surface of the clay.

The separation of pyrites from other minerals by electrostatic and electromagnetic processes was discussed by P. André,⁹ T. Crook, G. Rigg, P. Truchot, P. Rehbindler and co-workers, and A. W. G. Wilson.

The preparation of iron disulphide—pyrite and marcasite.—J. L. Proust, C. F. Bucholz and A. F. Gehlen, J. J. Berzelius, C. F. Rammelsberg, L. Gedel, and R. Scheuer obtained iron disulphide by heating a mixture of iron or ferrous

sulphide and sulphur below a red-heat. According to J. J. Berzelius, when ferric oxide or its hydrate, ferrosic oxide, ferrous carbonate, or one of the lower iron sulphides is exposed to the action of hydrogen sulphide at a temp. short of redness, a vigorous reaction at first occurs, and steam, sulphur dioxide, and hydrogen are evolved whilst a lower sulphide of iron is formed, which afterwards takes up more sulphur with the evolution of hydrogen. J. J. Berzelius also said that when an intimate mixture of ferrous sulphide with half its weight of sulphur is heated in a retort to a temp. short of redness, iron disulphide is formed as a bulky, yellow powder. J. J. Berzelius, C. Doelter, L. Gedel, T. G. Pearson and P. L. Robinson, and L. A. Sayce added that hydrogen sulphide at a low temp., between 100° and a red-heat, forms iron disulphide, but C. F. Rammelsberg added that the product is an oxysulphide, not the disulphide. F. Wöhler heated an intimate mixture of ferric oxide, sulphur, and ammonium chloride to a temp. a little above the sublimation point of the ammonium chloride, and obtained a residue consisting of small, brass-yellow octahedra and cubes of pyrite which could be separated from the rest of the powder by levigation. S. Meunier added that various salts of iron—*e.g.*, ferrous carbonate—can be employed in place of ferric oxide. F. Foreman, and E. Weinschenk obtained crystals by a similar process. C. F. Rammelsberg melted iron with an excess of sulphur, and obtained a mass similar to pyrites, and by the action of hydrogen sulphide on siderite or magnetite, between 100° and 500° , he obtained pseudomorphs of pyrite. J. Durocher passed a mixture of the vapour of ferric chloride and hydrogen sulphide through a red-hot porcelain tube, and obtained small cubic crystals; whilst F. Schlagdenhauffen also obtained the crystals by the action of the vapour of carbon disulphide on ferric oxide at a high temp. E. Glatzel heated in a retort an intimate mixture of phosphorus pentasulphide with twice its weight of anhydrous ferric chloride, until thiophosphoryl chloride was no longer evolved, and after levigation in water, isolated crystals of pyrite remained. According to N. Costeanu, sodium or potassium pentasulphide can be employed in place of phosphorus pentasulphide. H. N. Warren obtained pyrite by heating a mixture of ferric oxide and potassium thiocyanate. C. Doelter showed that in the experiments of J. Durocher, and C. F. Rammelsberg, the reaction occurs at about 200° , and that it is better to use amorphous ferric oxide than hæmatite or metallic iron. C. Geitner obtained brass-yellow crystals of pyrite by heating iron, magnetite, or ferric oxide and sulphurous acid in sealed tubes at 200° .

H. de Sénarmont heated a soln. of potassium or sodium polysulphide with ferrous or ferric sulphate in a sealed tube at 180° , and obtained a yellow product; and by heating precipitated ferrous sulphide with a soln. of hydrogen sulphide in a sealed tube, he obtained crystals of pyrite; a black precipitate obtained in this process is considered by L. Gedel to be ferric sulphide. E. T. Allen and co-workers represented the reactions: $\text{Fe}_2(\text{SO}_4)_3 + \text{H}_2\text{S} = 2\text{FeSO}_4 + \text{H}_2\text{SO}_4 + \text{S}$, and $\text{FeSO}_4 + \text{S} + \text{H}_2\text{S} = \text{FeS}_2 + \text{H}_2\text{SO}_4$. A. Schleede and H. Buggisch employed an analogous process; and C. O. Harvey boiled a soln. of ferrous sulphate with hydrogen sulphide, water, sulphur, and chalk: $\text{FeSO}_4 + \text{H}_2\text{S} + \text{CaCO}_3 = \text{H}_2\text{O} + \text{CO}_2 + \text{FeS}_2 + \text{CaSO}_4$. C. Doelter heated in sealed tubes a mixture of siderite, hæmatite, or magnetite with water saturated with hydrogen sulphide for 72 hrs. at 80° to 90° , and obtained cubic crystals of pyrite. Siderite gave the best results; only a small yield was obtained with magnetite. C. Doelter also heated ferrous chloride, water, and hydrogen sulphide in a sealed tube for 16 days at 200° , and he obtained pyrrhotite when air was excluded, and pyrite when some air was present. C. Doelter also noticed that crystals of pyrite were formed in his experiments on the solubility of pyrite in water, and in soln. of sodium sulphide. The black, amorphous precipitate formed by the action of alkali polysulphides on ferrous salts, is, according to E. T. Allen and co-workers, a mixture of ferrous sulphide and sulphur. This mixture, when heated, gradually passes into the disulphide, although some black precipitate remains unchanged even after heating for several days with an excess

of polysulphide at 100°. The influence of time is shown by heating systems with 3 grms. of ferrous sulphate, 2.5 grms. sodium sulphide, 0.75 gm. sulphur, and 100 c.c. of water at 100° for 2 and 7 days, when the products contained respectively 75 and 95 per cent. of pyrite. E. T. Allen and co-workers found that when the products are purified by boiling with 20 per cent. hydrochloric acid, the proportions of pyrite formed at 300°, 200°, and 100° were respectively 97, 71, and 51 per cent. Marcasite was absent, so that the remaining 3, 29, and 49 per cent. are amorphous disulphide. The evidence for the existence of the amorphous disulphide in the alkaline soln. is as follows: While the products of acidic soln. which contain the most marcasite are the best crystallized, those from alkaline soln. which contain the most disulphide are almost black, dull, and lustreless at the lower temp. The proportion of pyrite is increased by raising the temp., or prolonging the time of the reaction—both conditions are favourable to the production of an amorphous substance. Moreover, marcasite is not changed when it is heated several days with a soln. of sodium polysulphide at 300°. Hence, the first product of the union of sulphur and ferrous sulphide from an alkali polysulphide soln. is amorphous iron disulphide which slowly crystallizes into pyrite.

According to E. T. Allen and co-workers, the first action of hydrogen sulphide on a soln. of a ferric salt is to reduce the soln. with the simultaneous deposition of sulphur; and in closed vessels, when the hydrogen sulphide cannot escape or be oxidized, the reaction: $\text{FeSO}_4 + \text{S} + \text{H}_2\text{S} = \text{FeS}_2 + \text{H}_2\text{SO}_4$, occurs. The speed of this reaction is very small at ordinary temp., but at 200° it is comparatively rapid. When hydrogen sulphide and sulphur act on a soln. of ferrous sulphate, the crystals of the disulphide are small; their size is greater the higher is the temp.; other conditions—e.g., a slow reaction—favour the formation of large crystals. Thus, by arranging the experiment at 200° so that hydrogen sulphide was slowly given off from a thiosulphate soln., $\text{Na}_2\text{S}_2\text{O}_3 + \text{H}_2\text{O} = \text{Na}_2\text{SO}_4 + \text{H}_2\text{S}$, in the presence of a ferric salt, comparatively large crystals of a mixture of pyrite and marcasite were formed. In order that pyrite may be the principal product, the soln. should be neutral, or only slightly acid. The reaction which occurs when a mixture of ferrous sulphate and sodium thiosulphate is heated in a sealed tube at 90° to 200°, results in the formation of a mixture of sulphur and pyrite. The reaction can be symbolized: $4\text{Na}_2\text{S}_2\text{O}_3 + \text{FeSO}_4 = \text{FeS}_2 + 3\text{S} + 4\text{Na}_2\text{SO}_4$. It is possible that in the case of ferrous sulphate, the hydrogen sulphide from the thiosulphate reacts: $\text{FeSO}_4 + 4\text{H}_2\text{S} = \text{FeS}_2 + 3\text{S} + 4\text{H}_2\text{O}$; but since the pyrite is similarly formed with soln. of ferrous chloride, it is thought that ferrous thiosulphate is first formed: $\text{FeSO}_4 + \text{Na}_2\text{S}_2\text{O}_3 = \text{Na}_2\text{SO}_4 + \text{FeS}_2\text{O}_3$; and that this reacts: $\text{FeS}_2\text{O}_3 + 3\text{Na}_2\text{S}_2\text{O}_3 = \text{FeS}_2 + 3\text{S} + 3\text{Na}_2\text{SO}_4$. Pyrite was also synthesized by the thiosulphate reaction by W. Feld, and R. F. Carpenter and E. Linder. W. Mecklenburg and V. Rodt, and V. Rodt found that in the absence of air, ferric sulphide decomposes into pyrite and ferrous sulphide: $\text{Fe}_2\text{S}_3 = \text{FeS} + \text{FeS}_2$.

According to E. T. Allen and co-workers, hydrated ferric oxide along with 100 c.c. of water saturated with hydrogen sulphide, was heated in a sealed tube for 7 days at 140°, and the yellowish-brown product was boiled with 20 per cent. hydrochloric acid to remove hydrated ferric oxide and ferrous sulphide. About 90 per cent. of the remainder was pyrite, and 10 per cent. marcasite. Hydrated ferric oxide which has been dried at 100° is less susceptible to attack by hydrogen sulphide than the hydrate which has not been dried. In these cases, the pyrite is immediately formed by the direct union of sulphur and ferrous sulphide, as shown by C. Doelter,—the hydrogen sulphide water probably acts as a weak solvent; similarly also marcasite can be regarded as a product of the addition of sulphur to ferrous sulphide which gradually forms from the soln. Since pyrite can be formed by the action of sulphur on crystalline pyrrhotite, it follows, as pointed out by E. T. Allen and co-workers, that it is not the exact nature of the solid phase reacts with the sulphur, but rather the composition of the soln. in which it forms, which determines whether the product shall be pyrite or marcasite. A mixture of 2.2 grms. of artificial

pyrrhotite, 0.8 gram. of sulphur, 0.1 gram. of sodium hydrocarbonate, and 100 c.c. of water was saturated with hydrogen sulphide, and sealed in a glass tube. The composition of the soln. was similar to that of a warm "sulphur" spring, and it served as a solvent for the sulphur which was gradually absorbed by the pyrrhotite. The vessel was heated for 2 months at 70°, when the undecomposed pyrrhotite was removed by boiling the product with 20 per cent. hydrochloric acid. The dense, brass-yellow product contained all pyrite and no marcasite. The reaction proceeds more quickly at 300°; thus, a mixture of 5 grms. of pyrrhotite, 1.75 grms. sulphur, 0.2 gram. of sodium hydrocarbonate, and 100 c.c. of water saturated with hydrogen sulphide, was similarly treated for 4 days at 300°, when the product contained 95 per cent. pyrite. V. Rodt prepared pyrite by boiling a mixture of freshly-precipitated ferrous sulphide and sulphur suspended in water; and it is formed by the action of hydrogen sulphide on hydrated ferric oxide when the first product of the action is ferric sulphide, and if at an elevated temp., the ferric sulphide decomposes into iron disulphide. The reaction: $\text{Fe}_2\text{S}_3 \rightarrow \text{FeS} + \text{FeS}_2$, does not occur in the presence of substances having an alkaline reaction. A. L. T. Moesveld observed pyrite is formed in faintly-alkaline or neutral soln., and marcasite, in acidic soln. L. A. Sayce found that pyrite is formed when hydrogen sulphide, at about 300°, acts on ferric oxide (*q.v.*).

V. Rodt, and W. Feld observed that whenever sulphur and ferrous sulphide are boiled together in neutral or feebly acidic soln., pyrite is formed. E. T. Allen and co-workers found that the first product of the action of hydrogen sulphide on a soln. of ferric sulphate can be represented by: $\text{Fe}_2(\text{SO}_4)_3 + \text{H}_2\text{S} = \text{S} + 2\text{FeSO}_4 + \text{H}_2\text{SO}_4$, when the hydrogen sulphide is prevented from oxidation or escape—say, by confining the mixture in a sealed tube—a second reaction: $\text{FeSO}_4 + \text{S} + \text{H}_2\text{S} = \text{FeS}_2 + \text{H}_2\text{SO}_4$, occurs. The velocity of the latter reaction is slow at room temp., but faster at 200°. The product of the action at 200° for 2 days, is washed first with water, then digested with ammonium sulphide to remove the excess of sulphur, boiled with 20 per cent. hydrochloric acid, washed in an atm. of carbon dioxide, and dried in vacuo. Marcasite is the main product. Sulphuric acid is here a product of the reaction in which marcasite forms, and the concentration of the acid increases during the progress of the reaction. A greater initial concentration of acid favours the development of marcasite. Thus, with 5 grms. of ammonium ferrous sulphate, 100 c.c. of water saturated with hydrogen sulphide and,

Free H_2SO_4	0.50	0.57	0.78	1.18 gram.
Marcasite	57	75	90	92.5 per cent.
Pyrite	43	25	10	7.5 „

Working at different temp. with the same mixture, but with 0.17 gram. of free sulphuric acid, at 300°, 200°, and 100°, the products contained respectively 43, 68, and 92 per cent. of marcasite. This shows that the higher the temp., the greater is the proportion of pyrite. It was also observed that although a high concentration of acid favours the production of marcasite, there is for each temp. a certain critical conc. of acid which inhibits the reaction: $\text{FeSO}_4 + \text{H}_2\text{S} + \text{S} = \text{FeS}_2 + \text{H}_2\text{SO}_4$. This critical conc. of acid is smaller, the lower is the temp. It bears no relation to the solubility of the sulphide, for at room temp. the quantity is a fraction of 1 per cent., whereas at 200° it is between 3.5 and 5 per cent. during periods of a few weeks.

F. Wöhler heated marcasite and pyrite for 4 hrs. at about 445°, but observed no transformation of the one into the other, but the observations of E. T. Allen and co-workers showed that marcasite slowly changes into pyrite at this temp., and J. Königsberger and O. Reichenheim found a marked decrease in the electrical resistance of marcasite near 520° such that the resistance becomes of the same order as that of pyrite. They consider that their results prove that marcasite changes into pyrite, and that the change is irreversible. E. T. Allen and co-workers observed no evidence of any change at 300° and 350°, although

J. Königsberger and O. Reichenheim thought that the change begins between 250° and 300°. The heating curves, Fig. 628, show that between 500° and 600° marcasite undergoes a change which is accompanied by the evolution of heat.

A. Cavazzi considered that the heats of combustion of the two forms are the same, but in view of the heating curves, this can mean only that the method of measurement was not sensitive enough to detect a difference. The condition of instability of marcasite revealed by its possessing more energy, is in accord with the greater chemical activity of marcasite. For some unknown reason, monotropic forms often crystallize from some particular solvent, or within a limited temp. range, and the formation of marcasite in acidic soln. is an example of this. A rise of temp. hastens the monotropic reaction: marcasite \rightarrow pyrite; at low temp. it is immeasurably slow or zero; above 450°, it is fast enough to measure. Hence, it is possible that pyrite never changes to marcasite without first passing into soln., while the opposite change readily occurs.

H. V. Anderson and K. G. Chesley followed the change of marcasite into pyrite at 415° by observations on the X-radiograms. P. von Jereméeff, and J. R. Blum mentioned pseudomorphs of marcasite after pyrite, but E. T. Allen and co-workers' observations show that paramorphs of pyrite after marcasite are possible, but paramorphs of marcasite after pyrite are impossible.

Pyrite has a higher density than marcasite, and if H. le Chatelier's law—2. 17, 4—were applicable to irreversible changes, it should be possible to effect the transformation of marcasite to pyrite by pressure; but there is no warrant for assuming that press. favours all changes accompanied by a reduction in vol., irrespective of their reversibility. E. T. Allen and co-workers, however, found that no pyrite formation was observed when a few grams of marcasite were compressed for 5 hrs. at 10,000 atm. at ordinary temp., or when compressed at 2,000 atm. at 300° to 400°.

As just indicated, F. Wöhler obtained no evidence of the formation of marcasite by heating pyrite for 4 hrs. at 445°. Nor did C. Doelter succeed in synthesizing marcasite by heating a mixture of ferrous sulphate and carbon at a red-heat in a current of hydrogen sulphide, by the action of coal-gas and hydrogen sulphide on heated ferrous sulphate, or by the action of hydrogen sulphide on heated ferrous carbonate. He obtained twinned crystals of marcasite by treating ferrous sulphate with distilled water, with soda-lye, or with a soln. of sodium sulphide—but this has not been confirmed—*vide supra*. L. Michel reported that aggregates of what appeared to be rhombic marcasite were obtained as a by-product in synthesizing garnet, by heating in a graphite crucible at 1200° for 5 hrs. a mixture of titaniferous iron ore, calcium sulphide, silica, and carbon. The result has not been confirmed.

H. Schneiderhöhn,¹⁰ F. V. von Hahn, and F. Bernauer observed specimens of marcasite which appeared to contain the **colloidal iron disulphide**, presumably marcasite; and the hydrogel found in Miocene clays of the Melnikoff Estates, Samara, Russia, was named **melnikoffite**, *melnikowite*, or *melnikovite*, by B. Doss. The hydrogel was examined by H. Ehrenberg. Hydrated iron disulphide was studied by M. P. Tschirvinsky, L. M. Jegunoff, J. Habermann, and K. Andrée; and B. Doss observed that it occurred in a number of different localities. W. Feld showed that the hydrogel of ferrous sulphide can be converted into the hydrogel of iron disulphide by the sequence of reactions: $2\text{FeS} + 3\text{SO}_2 = 2\text{FeS}_2\text{O}_3 + \text{S}$; $\text{FeS}_2\text{O}_3 + 3\text{H}_2\text{S} = 4\text{S} + 2\text{H}_2\text{O} + \text{FeS} \cdot \text{H}_2\text{O}$; and $\text{FeS} \cdot \text{H}_2\text{O} + \text{S} = \text{FeS}_2 + \text{H}_2\text{O}$. B. Doss observed that the colloidal melnikoffite may be regarded as a stage in the transformation of hydrotroilite into pyrite: Troilite gel \rightarrow melnikoffite gel \rightarrow melnikoffite \rightarrow pyrite. E. T. Allen and co-workers observed that when an alkali polysulphide acts on a soln. of ferric sulphate, the formation of amorphous iron disulphide

FIG. 628.—Heating Curves of Marcasite and Pyrite.

precedes the formation of pyrite; J. D. Clark and P. L. Menaul found that crystalline pyrite is peptized by alkaline soln. in the presence of hydrogen sulphide; and F. V. von Hahn obtained a hydrosol by spluttering from the pyrite arc under water; if in a soln. of alkali-lye, the sol is very stable. Melnikoffite is black with a steel-grey lustre; its sp. gr. is 4.2 to 4.3; and its hardness 2 to 3. K. C. Berz suggested that melnikoffite is a mixture of sulphide and oxide. When heated in a dry tube, sulphur is sublimed. With boiling water, it is hydrolyzed forming ferrous sulphide and sulphur, while, according to L. Benedek, pyrite suffers this transformation between 300° and 400°. B. Doss represents the reaction: $\text{FeS}_2 = \text{FeS} + \text{S}$, and $\text{FeS} + 2\text{H}_2\text{O} = \text{Fe}(\text{OH})_2 + \text{H}_2\text{S}$. Melnikoffite is insoluble in water. Potash-lye decomposes the mineral to form orange-red hydrated ferric oxide. An alkaline soln. of bromine-water decomposes melnikoffite rapidly, whilst J. Lemberg found that pyrite is decomposed only slowly. A 10 per cent. soln. of iodine and potassium iodide strongly attacks melnikoffite. Dil. hydrochloric acid at ordinary temp. attacks it slowly, but when warmed, iron passes into soln., and a skeleton of sulphur remains. The mineral is peptized by a soln. of hydrogen sulphide, and likewise by a 10 per cent. soln. of sodium sulphide—note A. Terrell's and C. Doelter's experiments on pyrite—*vide infra*. Hot acetic acid has only a slight attack on the mineral; but it is dissolved by warm nitric acid. A soln. of potassium cyanide rapidly converts melnikoffite into soluble ferrocyanide, but pyrite under the same conditions is only slightly attacked.

The physical properties of pyrite.—Pyrite occurs in crystals or aggregates of crystals, and frequently in fine or granular masses. It sometimes occurs in radiating fibrous masses, in reniform or globular nodules, as well as stalactitic. The colour on fresh surfaces is nearly uniform, pale brass-yellow, and the streak is greenish-black or brownish-black. According to J. L. C. Schroeder van der Kolk,¹¹ the streak is pale brown to pale violet. H. du Bois observed pleochroism with a polished surface of the crystal; J. Königsberger studied the pleochroic reflection; and E. P. T. Tyndall observed no change in the reflecting power at low temp.

J. B. L. Romé de l'Isle, R. J. Haüy, A. G. Werner, and N. Steno showed that the many forms in which the **crystals** occur can be all derived from the cube, and that the crystals belong to the cubic system. E. T. Allen and co-workers found that the artificial crystals of pyrite show both the cubic and the octahedral faces, but both forms occur alone; pyritohedra were not observed. The faces were always warped and imperfect. The angles were close to the theoretical values. The isomorphism of pyrite with iron, nickel, and cobalt sulphoarsenides was discussed by C. F. Rammelsberg. The crystals of pyrite exhibit various forms of **twinning**. The twinning is that characteristic of penetration twins with parallel axes. The apparently simple crystals may really be supplementary twins. Even when the crystals occur in simple cubes the symmetry of the twinning is revealed by the well-marked striations which are parallel to alternate pairs of edges, so that the striations on these faces are at right-angles to those on the adjacent faces. The repetition of minute crystal faces, by what is called an oscillatory combination, sometimes tends to produce rounded faces. The faces of the octahedral forms are generally smooth and bright. The pentagonal dodecahedron is so characteristic of the crystals of pyrite, that the form is sometimes called the *pyritohedron*; while the dodecahedron is comparatively rare. The crystals are sometimes abnormally developed so that they are rod-like or acicular owing to their elongation in the direction of a cubic axis; and the crystals may be abnormally-developed with tetragonal or rhombic symmetry. In the so-called supplementary twinning, one crystal appears to project entirely through the other. Some pyritohedral crystals have their faces striated parallel to the cubic edges, and others have their faces striated perpendicular to those edges; the former are thermoelectrically positive to copper, and the latter, negative. Some crystals of pyrite are partly positive and partly negative.

The various crystal forms of pyrite were described by A. d'Achiardi, G. B. d'Achiardi, C. Arevalo, A. Arzruni, E. F. Ayres, V. L. Ayres, F. Azzini, F. A. Bannister, M. Bauer, F. Becke, J. Beckenkamp, G. Boeries, A. Breithaupt, A. Brezina, W. C. Brögger, A. Brunlechner, M. J. Buerger, L. Busatti, H. Buttgenbach, A. Cathrein, G. Cesaro, K. Chudoba, J. H. Collins, L. Colomba, J. D. Dana, E. Doll, C. Doelter, C. Düsing, H. Ehrenberg, J. Eyeran, G. Flink, A. Franzenau, A. Franzenau and L. Tokody, A. Frenzel, P. Gaubert, F. A. Genth, E. Glatzel, V. Goldschmidt and co-workers, G. Greim, H. F. Grondijs and C. Schouten, P. Groth, G. Häag and I. Sucksdorf, E. Hatle, A. C. Hawkins, R. Helmhacker, C. Hintze, W. H. Hobbs, H. Höfer, E. Hussak, S. Ichikawa, P. von Jereméeff, K. Jimbo, G. Kalb, G. A. Kenngott, N. von Kokscharoff, J. Krenner and K. Zimanyi, A. Lacroix, H. Laspeyres, G. Leonhard, A. Liffa, A. Liveridge, M. Löw and co-workers, G. Lowe, O. Luedecke, A. Martelli, B. Mauritz, L. Maros, W. J. Mead and C. O. Swanson, R. Meli, H. Miers, L. Miropolsky, A. J. Moses, O. Mügge, L. F. Navarro, P. Niggli, A. E. Nordenskjöld, C. Palaché and H. O. Wood, U. Panichi, R. L. Parker and W. O. Kennedy, S. L. Penfield, L. S. Ramsdell, G. vom Rath, R. Reinicke, J. W. Retgers, P. y Rico, A. F. Rogers, G. Rose, V. Rosicky, A. Sadebeck, J. Samojloff, F. Sandberger, F. Sansoni, E. Scacchi, F. Scharff, C. Schmidt, E. Schnaebele, W. B. Smith, G. Smolar, L. J. Spencer, A. Stelzner, G. Strüver, E. Tacconi, L. Tokody, F. D. Tosas, H. Traube, C. Travis, R. Tronquoy, G. Tschernak, P. Tschirwinsky, G. H. F. Ulrich, T. Wada, M. Websky, E. Weinschenk, H. P. Whitlock, F. J. Wiik, G. H. Williams, D. F. Wiser, K. Zerrenner, K. Zimanyi, etc.

The **cleavages** (100) and (111) are indistinct. The **corrosion figures** were investigated by A. Johnsen, V. Pöschl, F. Becke, E. H. Kraus and J. D. Scott, E. Thomson, B. Granigg, M. Leo, J. Lemberg, S. Ichikawa, L. Tokody, G. Tammann and W. Krings, G. Rose, and H. Schneiderhöhn. S. Ichikawa noted that the symmetry of all etching figures corresponds with the hemihedral symmetry of the crystals. The pits and striations are closely related. The pits on pyrite crystals, with natural etchings, are accompanied by striations on the same faces. If the etching progresses farther, eye-shaped pits are produced with a centre of tetragonal pyramidal form at the extremities of the binary hemihedral axis of symmetry so that the etched crystal is modified to a cube-like form, then gradually modified to a tetrahedral form, and is at last wholly dissolved away. M. Watanabe found that the cube faces of pyrite are corroded about 1.3 times quicker than the octahedron faces. The **gliding-plane**, (121), was noted by G. Smolar, but this has not been confirmed. K. Veit studied the subject. The microscopic appearance of polished sections was described by A. A. Julien, B. Granigg, F. N. Guild, and H. Schneiderhöhn. K. Veit, F. D. Adams, and M. J. Buerger studied the deformation of the crystals by pressure.

W. L. Bragg studied the **X-radiograms** of pyrite, and the results were in agreement with the assumption that the iron atoms are arranged in a face-centred

lattice; and, if a series of non-intersecting three-fold axes are chosen, one passing through each iron atom, so that each small cube has a single diagonal which is a three-fold axis of symmetry. Each cube contains one sulphur atom which lies on the diagonal near the empty corner, and divides the diagonal in the ratio 1:4. P. Niggli represented the lattice by Fig. 629, in accord with the scheme for closest packing. The simple formula of pyrite is taken to be in accord with that of J. Loczka, and in the diagram the black dot is considered as the centre of gravity of the S_2 -atoms. In that case, the space-lattice resembles that for sodium

FIG. 629.—Space-lattice of Pyrite.

chloride. J. W. Gruner said that the S-S radicles in pyrite can be compared to dumb-bells whose axes are parallel to the three-fold cubic axes. The radicles are so distributed that each octant of unit cube contains half a radicle; but the axes of adjoining radicles (which are less apart than the length of the edge of unit cube) are not parallel. Each S-atom of the radicle forms the corner of three tetrahedrons which are symmetrical with respect to the three-fold axis in which the radicle lies. These slightly distorted tetrahedra are linked

to other sets of tetrahedra directly, as well as by means of radicles. This arrangement cannot well be shown in a two-dimensional diagram. The centres of gravity of the dumb-bells are in the positions of face-centred cubes, and, therefore, the radicles are in a close-packing. This gives a very dense structure for pyrite. Zinc blende has a unit cell nearly the same size as pyrite, and each cell contains four molecules, but pyrite has twice as many atoms of sulphur in the same volume. E. Onorato found both the (210)-spacings are equal to 2.406 Å.; R. Juza and W. Biltz observed no evidence of intermediate forms in the reaction: $\text{FeS}_2 \rightarrow \text{FeS} + \text{S}$ —*vide infra*. The structure of the space-lattice has been also discussed by H. V. Anderson and K. G. Chesley, A. Reis, M. L. Huggins, F. Haag, R. Scharizer, N. H. Kolkmeijer, P. F. Kerr, F. R. and K. R. van Horn, and J. Beckenkamp. P. P. Ewald and W. Friedrich calculated the density to be 5.38, the side of the elementary cube $a = 5.40 \times 10^{-8}$ cm.; the distance between two iron atoms in the direction (110) is 3.82×10^{-8} cm.; the distance between the two sulphur atoms of the S_2 -complex, in the direction of the trigonal axis, (111), is 2.06×10^{-8} cm., which is closer than it is in other known sulphides; and the distance of the centre of gravity of the S_2 -complex from the centre of gravity of the iron atom is 2.70×10^{-8} cm. in the direction of the (001)-face. H. M. Parker and W. J. Whitehouse gave for the spacing of the cell, 5.405 Å.; for the distance between the centres of adjacent sulphur atoms, 2.14 Å.; and between adjacent sulphur and iron atoms, 2.26 Å. R. von Nardroff calculated for the density, 5.40560; and I. Oftedal, 5.414. M. L. Huggins studied the effect of the space-lattice structure on the properties of pyrite; P. Niggli, the electronic structure; J. R. Tillman, the inner potential; and J. Forrest, the magnetic lattice.

Numerous observations have been made on the **specific gravity** of pyrite. G. A. Kenngott found values ranging from 4.807 to 5.028; V. Pöschl, 5.169 to 4.903; A. Breithaupt, 4.960 to 5.158; F. E. Neumann, 5.042; A. S. Herschel and G. A. Lebour, 4.66; E. Madelung and R. Fuchs, 4.9803; H. N. Stokes, 5.041 to 4.563; J. D. Dana, 4.95 to 5.10; J. Samojloff, 4.990; E. C. Schiffer, 5.016; C. F. Rammelsberg, 4.826 to 4.919—best representative value 5.00; A. A. Julien, 5.01; F. Kollbeck, 4.85 to 4.95; and C. U. Shepard, 4.863. According to E. T. Allen and co-workers, the sp. gr. of artificial pyrite is 5.02, which is very near the value of pyrite from Elba; and V. Rodt gave 4.588 at $18^\circ/4^\circ$. F. Gieseler gave 4.838 at $25^\circ/4^\circ$ for the sp. gr. of the synthetic disulphide; and calculated 24.8 for the mol. vol., and 8.9 for the at. vol. of the contained sulphur. This means a contraction of 41.4 per cent. during the formation of the compound. R. Juza and W. Biltz observed the sp. gr. at $25^\circ/4^\circ$ and mol. vol.:

FeS_n . . .	1.942	1.907	1.720	1.450	1.345	1.187	1.118	1.068	1.028
Sp. gr.. . .	4.978	4.975	4.896	4.769	4.725	4.605	4.593	4.637	4.736
Mol. vol. . .	23.7	23.5	22.7	21.4	20.9	20.4	19.95	19.4	18.7

and the results are plotted in Fig. 630. The results of the X-radiograms are indicated at the bottom. W. H. Goodchild, J. J. Saslawsky, N. S. Kurnakoff and S. F. Schemtschuschny, and I. Maydall also calculated values for the vol. contraction which occurs during the formation of pyrite from its elements; and F. J. Malaguti and J. Durocher attempted to correlate the sp. gr. with the crystalline form, but neither G. A. Kenngott nor A. A. Julien thought there was any good reason for adopting the suggestion. The **hardness** of pyrite is between 6 and 6.5; A. A. Julien gave 6.51. Pyrite is one of the hardest of the sulphide minerals. Iron pyrites is so hard that it will take a good polish, and some is used for cheap jewellery, when it is cut in the form of a flat rosette. Polished plates of pyrite have been found in the

FIG. 630.—Molecular Volumes of the Iron Sulphides.

graves of the Incas of ancient Peru, and they are now known as *Incastones*; they are thought to have been used as mirrors. F. Pfaff gave 58 for the boring hardness of pyrite on the (100)-face when that of talc is unity. According to V. Pöschl, the scratching hardness of pyrite is 182.2 and 199.1 respectively under loads of 20 and 50 grms. when the hardness of topaz is 1000; and with one and the same face, the hardness does not vary with the direction of scratching. The hardness of different faces of one and the same crystal is the same when the surface conditions are constant, differences occur when there is a change in the structure. C. Viola discussed the cohesion of the crystals; and although G. Smolar regarded (12 $\bar{1}$) as a gliding plane, O. Mügge observed no change under a press. of 35,000 atm., but cleavage on the (001)-face appeared. Pyrite, at ordinary temp., is very resistant towards high press. F. D. Adams found that under a compression of 43,000 lbs. applied in 17 minutes, pyrite crushed to powder without showing any signs of plastic deformation, but M. J. Buerger obtained evidence of the phenomenon. W. Voigt measured the **elastic constants** of pyrite, and found for the elastic modulus 35,300 kgrms. per sq. mm. in the direction of a cubic face, and 25,300 kgrms. per sq. mm. in the direction of the rhombic dodecahedron face, the torsion modulus in the direction of surface is 10,750 kgrms. per sq. mm., and the compressibility is 0.000114 kgrm. per sq. mm. F. D. Adams gave 0.70×10^{-6} for the **compressibility** of pyrite; P. W. Bridgman gave $0.6728-1.95 \times 10^{-12}$ at 30°, and $-0.6716-1.95 \times 10^{-2}$ at 75° for press. up to 12,000 kgrms. per sq. cm.; L. H. Adams and E. D. Williamson found the coeff. of compressibility of pyrite to be $\beta = 0.71 \times 10^{-6}$ for press. ranging from 0 to 10,000 megabars; and for $d\beta/dp$, L. H. Adams gave $-0.0_{11}4$; whilst E. Madelung and R. Fuchs obtained $\beta = 0.0_{6}71$; and W. Voigt, $\beta = 0.0_{5}113$. L. Hopf and G. Lechner gave for the **velocity of sound** in absolute units, 5.43×10^5 ; and A. Eucken, 5.020×10^5 .

According to H. Fizeau,¹² the coeff. of **thermal expansion** of pyrite at 40° is $\alpha = 0.000009071$ when taken at right-angles to a natural face of the cube, and 0.00000908 when taken in a group of crystals, without reference to any common direction. F. Pfaff gave 0.000010084 for the linear coeff. between 0° and 100°; H. Kopp gave 0.000034 for the coeff. of cubical expansion between 15° and 47°. S. Valentiner and J. Wallot observed that between -25.2° and 18.5°, the linear coeff. $\alpha = 0.0_{5}843$; between -46.2° and -25.2°, $0.0_{5}773$; between -70.5° and -46.2°, $0.0_{5}709$; between -131.9° and -104.3°, $0.0_{5}516$; between -154.9° and -131.9°, $0.0_{5}392$; and between -175.2° and -154.9°, $0.0_{5}295$. The subject was studied by E. Grüneisen. H. de Sénarmont found the **thermal conductivity** of pyrite to be large. F. E. Neumann found the **specific heat** of pyrite to be 0.1267 to 0.1279; A. de la Rive and F. Marcet gave 0.1396; A. S. Herschel and G. A. Lebour, 0.125; H. V. Regnault, 0.1301 between 14° and 100°; H. Kopp, 0.1230 to 0.1238 between 18° and 47°; J. Thoulet and H. Lagarde, 0.13029; J. Joly, 0.1301 to 0.1306 between 12° and 100°; A. Sella, 0.1460; S. Pagliani, 0.1295 between 20° and 100°; and K. Bornemann and O. Hengstenberg, 0.1284 between 0° and 100°, and 0.1290 for a sample with 1 per cent. of SiO₂. K. Försterling calculated values from the elastic constants and the vibration frequency; and I. Maydell studied the mol. ht. A. Eucken and F. Schweser gave for the sp. ht. between -189.1° and -251.4°, and R. Ewald, between -135° and 28°—the full collection is given by H. Miething:

	28°	-38°	-135°	-189.1°	-216.2°	-243.0°	-251.4°
Sp. ht.	0.1219	0.1087	0.0640	0.0259	0.0079	0.0012	0.00054
Mol. ht.	14.64	13.04	7.63	3.11	0.952	0.139	0.0648

According to H. Rose, J. J. Berzelius, B. G. Bredberg, and C. F. Rammelsberg, when pyrite is heated not very strongly in a closed vessel, it dissociates with the evolution of sulphur, and at a higher temp. passes into ferrous sulphide (*q.v.*); and, according to J. L. Proust, the residue retains the form and colour of the original pyrites, though it is more bulky. The product is dull, and exhibits surface

cavities formed by local fusion, and it may be crumbled to pieces when squeezed between the fingers. F. Fouqué and A. Michel-Lévy added that the product is pulverulent and not crystalline. The **thermal dissociation** of pyrite into pyrrhotite and sulphur vapour was studied by E. T. Allen and co-workers, and A. F. Gill

FIG. 631.—The Vapour Pressures of Decomposing Iron Disulphide.

FIG. 632.—The Vapour Pressures of Pyrites.

—*vide supra*. E. Arbeiter observed that sulphur distils off when the pyrite is heated in vacuo. O. Mügge discussed the thermal contact metamorphosis of pyrites in clay shales, etc.; and W. Eitel, the passage of pyrite into pyrrhotite. G. Tammann and G. Bätz observed a break in the heating curve at 684° due to the loss of sulphur. E. T. Allen and co-workers found that the dissociation proceeds slowly at about 575°, and rapidly at 657° to form $\text{FeS}(\text{S})_n$; and this in an atm. of sulphur when the **dissociation pressure** is 1 atm. at 689°. W. Hempel and C. Schubert, and C. Schubert said that dissociation begins at 480°, and is ended above 1400°; and E. Kothny, that dissociation begins at 200°, and at 700°, in an inert gas, $p=1$ atm.; O. Barth found the dissociation begins at 350°, and when air is excluded, $p=1$ atm. at 600°; and J. Joly, at 450°. C. Schubert measured the dissociation press., and L. H. Bergström found the dissociation temp. to be 800°, at 40 to 60 atm. press. E. T. Allen and R. H. Lombard represented their observations on the dissociation press., p mm., by $\log p = -191942 \cdot 61 T^{-1} - 434 \cdot 195075 \log T + 1497 \cdot 56707$; the observed results were:

	575°	595°	610°	625°	645°	665°	672°	680°	689°
p	0.75	3.5	13.5	36.3	106.5	251	243	518	760

The results are plotted in Fig. 633. L. d'Or found the partial press., p mm., of S_2 is related to the absolute temp. between 548° and 676° by $\log p = -13 \cdot 380 T^{-1} + \log T + 13 \cdot 8205$. The observed and calculated results were:

		601°	619°	654°	664.5°	670°	676°
p	Calc.	28.5	(59)	226	331	408	500
	Obs.	30	59	223.5	333.5	413	504.5

The partial press., p , of the sulphur in its different forms were:

		548°	601°	619°	637°	654°	676°
p	S_2	2.8	30	59	119	223.5	504.5
	S_6	0.001	0.14	0.5	1.95	6.65	32.5
	S_8	0.001	0.002	0.01	0.157	0.25	2.0

A. C. Halferdahl gave $\log p = -9912 \cdot 09 T^{-1} + 29 \cdot 8543 \log T - 757084$. M. G. Raeder gave for the dissociation press., p mm., $\text{FeS}_2 = \text{FeS} + \text{S}$:

		590°	612°	637°	651°	663°	672°	680°	686°
p		2.8	22	73	140	250	393	575	772

FIG. 633.—The Dissociation Pressure of Pyrite.

G. Marchal observed that the dissociation of pyrite in vacuo begins at 500° ; it is rapid at 550° ; and is completed in 8 hrs. at 670° to 680° , or in 2 hrs. at 850° . At 1200° , the residue is a mixture of ferrous sulphide and a little iron. Dissociation is very rapid in an atm. of nitrogen at 850° . R. Juza and W. Biltz's results are summarized in Fig. 632. The dotted curve and inner ordinates refer to the vap. press. of iron disulphide at different temp. The results of the observations on the X-radiograms are indicated at the bottom. Observations were also made by H. Kamura, F. de Rudder, and M. G. Raeder (Fig. 631). The results of W. F. de Jong and H. W. V. Willems, by X-radiograms, and of L. d'Or, by absorption spectra, show that the dissociation is a reversible reaction involving only two solid phases, FeS and FeS_2 . C. Fontana thought that Fe_3S_4 exists, but the X-radiograms show no evidence of this.

R. Cusack said that the **melting-point** of pyrite is 642° ; J. Joly gave 450° ; but, according to L. Benedek, when pyrite is heated to redness in an inert atm., say of carbon dioxide, it loses half its sulphur to form ferrous sulphide, and a similar result is obtained at 300° to 400° in an atm. of steam. Hence, pyrite decomposes before it reaches the m.p. J. Baumann calculated the **temperature of combustion** or the temp. of the flame produced by burning pyrite: $2\text{FeS}_2 + 11\text{O} = \text{Fe}_2\text{O}_3 + 4\text{SO}_2$, and found 1216° ; this value is scarcely half as great as that given by F. Bode. J. S. Doting obtained 965° ; and F. de Rudder and M. Ferrer pointed out that the temp. is smaller if pyrite be taken as FeS_2 rather than as $\text{FeS} + \text{S}$. A. Cavazzi gave for the **heat of combustion** or **oxidation** of pyrite, 1.55 Cals. per gram; W. H. Emmons, 2.7 Cals.; and E. E. Somermeier, 1.557 Cals. E. T. Allen and R. H. Lombard did not succeed in calculating satisfactory values for the heat of dissociation from the observed dissociation data because of the change in the density of sulphur vapour with press., and on account of the variation in the composition of the solid phase, pyrrhotite. H. Kamura calculated from the observed absorption of heat, the **heat of formation** ($\text{FeS}, S_{\text{gas}}$) = 18.611 Cals.; W. G. Mixter observed ($\text{FeS}_{\text{amorphous}}, S_{\text{gas}}$) = $\text{FeS}_{2\text{cryst.}} + 16.7$ Cals.; or (Fe_2S) = 35.5 Cals. F. de Rudder and M. Ferrer gave ($\text{FeS}, S_{\text{gas}}$) = 18.513 Cals.; and H. Kamura, 18.611 Cals. L. d'Or gave $2\text{FeS}_2 = 2\text{FeS} + \text{S}_2 - 61$ Cals., and the energy of fixation of the first sulphur atom is 90.5 Cals., and that of the second, 82.5 Cals. For sulphur in the gaseous form, the values calculated for the heat of formation are: ($\text{FeS}, \frac{1}{2}\text{S}_2$) = 30.5 Cals.; (FeS, S) = 81.5 Cals.; (Fe, S_2) = 69.5 Cals.; and ($\text{Fe}, 2\text{S}$) = 171.5 Cals. F. de Rudder gave 18.518 Cals. for the heat of dissociation. A. C. Halferdahl found the heat of decomposition of pyrites to a solid soln. of ferrous sulphide and sulphur, to be -10 Cals. at 575° to 680° . He also gave, at room temp., $7\text{FeS}_2 \rightarrow \text{Fe}_7\text{S}_8 + 3\text{S}_2 - 8910$ cal.; and at 625° , $2\text{FeS}_2 \rightarrow 2\text{FeS} + \text{S}_2 - 34,260$ cal. K. K. Kelley studied the **entropy**.

The **index of refraction** for X-rays calculated by R. von Nardroff,¹³ B. Davis and R. von Nardroff, and B. Davis was found to be 3.35×10^{-6} for MoK α -rays, and 2.87×10^{-6} for the MoK β -rays; and 17.6×10^{-6} for the CuK α -rays, and 13.2×10^{-6} for the CuK β -rays. W. W. Coblentz measured the ultra-red **reflecting power** of pyrite, and found that it gradually increased from 25 per cent. at 2μ to 34 per cent. at 12μ —hatched line, Fig. 634. The low reflection at 2μ was attributed to lack of polish since another sample had a constant reflecting power from 3μ to 14μ of about 32 per cent. He also found the curve for the ultra-violet reflecting power to be that indicated in Fig. 634, which coupled up the observations of E. P. T. Tyndall. The effect of ageing on the optical properties of the surface in the region 240 to 320 $m\mu$ is shown by the dotted line, Fig. 634. The subject was studied by J. Königsberger and co-workers, and W. Ehrenberg and co-workers.

FIG. 634.—The Reflecting Power of Pyrite.

A. de Gramont studied the **spark spectrum**; and G. E. Claussen, the spark and **arc spectrum**. C. Doelter found that pyrite is opaque to the **X-rays**; H. Raether studied the action of canal rays; and K. R. Dixit, the potential of pyrites for electronic diffraction. G. A. Lindsay and H. R. Voorhees, and S. Tanaka and G. Okuno studied the X-ray absorption spectrum; B. Davis and R. von Nardroff, the refraction of the X-rays; P. de la Cierva and J. Losada, the reflection of X-rays; O. Stelling, the absorption of X-rays; and H. Raether, the diffraction of electrons. J. O. Perrine found that no fluorescence is produced in ultra-violet rays. A. Pochettino observed that pyrite shows a bluish-green **cathodoluminescence**; and J. Calafat y Léon, a violet **thermoluminescence** when the powder is strewn on a hot, but not red-hot, metal plate; A. Karl studied the **triboluminescence**. A. Rohde found that the **photoelectric effect** with pyrite is greater than that of pyrrhotite or of marcasite. A. Meissner found that when pyrite, in an electric field of 1000 to 2000 volts, is heated to 135°, there is produced a **pyroelectric effect** of 3·7 volts. F. Kirchner and H. Raether studied the dispersion of cathode rays by the crystal. M. von Laue and E. Rupp observed no difference in the electron diffraction from different faces of the crystals. P. Gaubert, E. T. Wherry, A. Schleede and H. Buggisch, J. N. Frers, and H. S. Roberts and L. H. Adams studied its use as a **radio-detector**.

R. J. Haüy¹⁴ observed that when pyrite is rubbed with a piece of cloth, the **frictional electricity** is negative. H. F. Vieweg studied the subject. F. Beijerinck, and R. G. Harvey found that the **electrical conductivity** of pyrite is good. J. Königsberger and O. Reichenheim gave 0·00381 mercury unit for the sp. conductivity of pyrite at 20·5°; H. Löwy obtained a higher value. The **electrical resistance** of pyrite at 40° is 1·282 ohms, when that of marcasite is 239·5 ohms. Observations were made by J. Pelletier, R. W. Fox, F. Braun, E. van Aubel, A. Abt, C. Bedel, J. F. L. Hausmann and F. C. Henrici, M. Faraday, W. Skey, H. Dufet, and H. Meyer. O. Reichenheim, and K. Baedeker gave 0·024 ohm for the sp. resistance at 0°; and J. Königsberger and co-workers found that the conductivity of pyrite is 500 times that of marcasite, and that the electrical resistance, R , of pyrite, parallel to the b -axis, and at θ° , can be represented by $R=0\cdot0240(1+0\cdot00385\theta+0\cdot000037\theta^2)e^{-24\theta/(\theta+273)273}$. The observed results are:

	-78°	20°	85°	121°	260°	340°
R	0·0251	0·0240	0·0279	0·0300	0·0357	0·0388

Hence, the resistance increases slowly up to about 350°, and then reverses. The transition point corresponds with P. Weiss' abrupt fall in the ferromagnetism. It is assumed that an allotropic modification forms between 300° and 400°. According to J. Königsberger and K. Schilling, the absolute electrical resistance per c.c. of a very pure sample of native iron sulphide, FeS_2 , perpendicular to the c -axis, fell from 0·000802 at -189° to 0·000256 at 277°, and 0·000262 at 310°, and at higher temperatures, the resistance increases a little. The electrical resistance, measured parallel to the c -axis, falls from 0·00107 at -188° to about 0·000387 at 350°, and this represents the range of stability of what is called **α -pyrites**; the resistance rises from 0·000380 at 350° to 0·000375 at 445°. Above the transition point, 348°-350°, the stable form is called **β -pyrites**. The transition point for the electrical resistance corresponds with P. Weiss' abrupt fall in the ferromagnetism at about 348°. B. Beckmann gave 0·00294 for the sp. resistance in ohms at 0°, and observed that the ratio $R:R_0=1\cdot063$ at 15·8°, and 0·390 at -258°; or:

	100·9°	54·2°	44·5°	14·6°	0°	-78·6°	-193°
R	0·1437	0·1235	0·1192	0·1070	0·1010	0·0733	0·0513 ohm.

In the vicinity of 0°, $R=R_0(1+0\cdot00353\theta+0\cdot0_56\theta^2)$. A. Wesely, F. Streintz and co-workers, and J. Königsberger and co-workers, emphasized the increase in the resistance produced by surface films. The minimum observed in the resistance curve by J. Königsberger at -10° was not confirmed by B. Beckman; nor did

A. Wesely confirm J. Königsberger's observations of a decrease in the resistance at 360°. F. Streintz and A. Wesely gave 0.0023 to 0.0035 for the temp. coeff. of the resistance; and B. Beckman gave 0.00353 at 0°, and he represented the resistance as a function of the temp. by $R=R_0e^{a\theta}$, where R is the resistance at θ° ; R_0 the resistance at 0°; and a , the temp. coeff. B. Beckmann found that:

	-19.3°	-78.6°	44.5°	54.2°	100.9°
$R : R_0$	0.508	0.726	1.180	1.223	1.422

F. Streintz and A. Welik observed that press. exerts a marked influence on the results; and B. Beckman gave for the effect of pressure, p atm., when $R=0.1010$ ohm,

$\frac{p}{\delta R/R}$	770	1255	1860	2390	2550
	0.0182	0.02915	0.04215	0.05305	0.05720

P. Collet observed a residual e.m.f. opposed to the current through the crystal, and the polarization effect may be referred to thermoelectric phenomena. C. W. Heaps found that the resistance is not influenced by a magnetic field. J. Königsberger and co-workers, and C. Doelter made observations on the theory of the electrical conductivity of pyrite. K. Fischbeck studied the electrolytic resistance of pyrites; and S. Borowik, the electrolytic valve action.

T. J. Seebeck made some observations on the **thermoelectric force** of pyrite; and W. G. Hankel found that the thermoelectric force of the (110)- or the (111)-face of pyrite towards copper is positive, whilst the (210)-face is partly positive and partly negative. H. Marbach also found some crystals of pyrite are positive, others negative; and A. Schrauf and E. S. Dana observed that most of the samples of pyrite which they examined were negative towards copper. The subject was examined by G. Strüver, H. Sutton, M. Kimura and co-workers, and K. Baedeker. G. Rose supposed that there is a relation between the hemihedry of the crystals of pyrite and their thermoelectric behaviour, but C. Friedel considered that this has not been established; the subject was discussed by J. Curie, J. Stefan, and J. Beckenkamp. W. Ogawa found that a current of 13,000 μ volt was developed with a couple of copper and pyrite. A. M. Iljeff observed that a cylinder of compressed powder of pyrite between two copper electrodes gives a thermoelectric current flowing in the direction of the fall of temp. J. Königsberger and J. Weiss observed a thermoelectric force of 0.000129 volt between 20° and 80°; and 0.000200 volt at 50°, where the current flowed from the pyrite to the copper. A. Abt examined the thermoelectric force between pyrite and chalcopyrite. W. H. Eccles studied the Peltier effect. E. T. Wherry found pyrite is a good **radio-detector**; and the subject was discussed by W. Ogawa, A. C. Hawkins, P. Glaubert, F. Frey, A. Schleede and H. Buggisch. J. N. Frers studied the system $\text{FeS}_2\text{-PbS}$; $\text{FeS}_2\text{-Pt}$, and $\text{FeS}_2\text{-ZnO}$.

W. Skey found that in sea-water, the **electromotive series** of the sulphides is: FeS , MnS , ZnS , SnS_2 , HgS , Ag_2S , PbS , Cu_2S , FeS_2 , Sb_2S_3 , so that pyrite is positive towards galena. R. C. Wells found that the **electrode potential** of pyrite in $N\text{-KCl}$ is 0.90 volt; in $N\text{-H}_2\text{SO}_4$, 0.95 volt; in $N\text{-NaOH}$, 0.14 volt; and in $N\text{-Na}_2\text{S}$, -0.17 volt. K. R. Dixit studied the inner potential; and H. B. Bull and co-workers, the electrokinetic potential. M. E. Conrad found that the **electromotive force** of pyrite is positive and of zinc negative in soln. of potassium or sodium hydroxide, and sulphuric acid, and R. Zuppinger found the effect is diminished by a rise of temp. V. H. Gottschalk and H. A. Buehler gave for the e.m.f. in volts of the minerals against copper in distilled water: marcasite, 0.37; chalcopyrite, 0.18 to 0.30; pyrite, 0.18; bornite, 0.17; hæmatite, 0.08 to 0.26; stibnite, -0.17 to 0.6; and zinc -0.83. A. Lipschitz and R. von Hasslinger found pyrite positive against a calomel electrode with an electrolyte of sulphuric acid with and without ferrous and ferric sulphates. V. H. Gottschalk and H. A. Buehler found that the potential of pyrite against copper in distilled water is 0.18 volt; and that with pyrite and galena in distilled water, the

pyrite is not attacked, and the galena is attacked; with sphalerite in place of galena, the sphalerite is attacked. R. C. Wells found that in the cell pyrite | $N\text{-Fe}_2(\text{SO}_4)_3$ (acidified) | sodium sulphide | pyrite, the e.m.f. after 0.1, 1.0, 5.0, and 10.0 min. were respectively 1.04, 1.02, 1.00, and 1.00 volt. G. Tammann found that with pyrite against $4N\text{-ZnSO}_4$ and zinc, the e.m.f. was 1.26 volt; against a sat. soln. of lead chloride and lead, 0.65 volt; $2N\text{-CuSO}_4$ and copper, 0.20 volt; and a sat soln. of silver sulphate and silver, 0.03 volt. G. N. Libby found that a pyrite anode in a cell of the Bunsen type gave twice the voltage of a cell with zinc blende as anode. A. Matsubara and J. Takubo studied the cathodic behaviour of pyrite.

K. G. Emeléus and J. W. Beck found the normal cathode fall of potential of iron pyrites, in volts, in:

Volts	Argon	Neon	Nitrogen	Oxygen	Air
	222	168	288	373	314

and that a single crystal behaves like an ordinary polycrystalline metal in the glow discharge when used as a cathode. They calculated the work-function of pyrite for electrons to be 4.8 volts.

In the **electrolysis** of pyrite suspended in molten potassium hydroxide, E. F. Smith noted that with a nickel crucible as cathode, and a platinum wire as anode, about half the sulphur is oxidized; with marcasite, oxidation is complete. R. Saxon observed that with finely-powdered pyrite in 10 per cent. sulphuric acid, with iron as cathode, carbon as anode, both ferrous and ferric sulphates appear in the electrolyte, and if an iron anode is used, only ferrous sulphate is formed. He also noticed that if pyrites be immersed in a soln. of ammonium sulphate and chloride, and subject to electrolysis whilst the pyrites is in contact with the carbon electrode, iron passes into soln. I. Bernfeld observed that with a pyrite anode in acidic soln., iron goes into soln., and with small current densities sulphur is deposited on the anode, and with large current densities, sulphuric acid is formed; with pyrite as anode in alkaline soln., iron is converted into hydroxide and all the sulphur forms sulphuric acid; with pyrite as cathode in acidic soln., hydrogen sulphide appears at the cathode; and with pyrite as cathode in alkaline soln., sulphur forms alkali sulphide. K. Fischbeck studied the cathodic reduction of pyrite in 2 per cent. sulphuric acid; M. Padoa and B. Zanella, the electrolysis of soln. of ammonium or sodium chloride and ammonium thiocyanate soln. with a pyrite anode, whereby the iron goes into soln. in the ferric state; and R. C. Wells, the anodic and cathodic polarization of pyrite in soln. of potassium chloride.

A. W. Smith¹⁵ found that the **Hall effect** with pyrite increases proportionally with the magnetic field; and G. Nicolai gave for field of H gauss:

H	9,150	10,100	11,150	12,200	13,300	14,400
Hall constant	-21.7	-22.9	-28.0	-33.0	-38.0	-42.0

The **magnetic properties** of pyrite were examined by J. J. Berzelius,¹⁶ T. J. Seebeck, M. Faraday, and C. B. Greiss. F. Gieseler said that the pure sulphide is non-magnetic. J. Huggett and G. Chaudron also said that pyrite is non-magnetic and that it undergoes oxidation at 400° . R. Juza and W. Biltz observed the susceptibility of different sulphides, and the results are summarized in Fig. 635, along with the results of observations on the X-radiograms. According to F. Stutzer and co-workers, the **magnetic susceptibility** of pyrite is 4.53×10^{-6} vol. unit; and L. C. Jackson said that the susceptibility is independent of the temp.; and after making allowance for the diamagnetic properties of the sulphur atoms in iron pyrites, the iron atom possesses a small, residual, positive magnetic moment. W. R. Crane gave

FIG. 635.—The Magnetic Susceptibility of the Iron Sulphides.

1.860×10^{-6} to 159×10^{-6} for the mass magnetic susceptibility of pyrite; and F. Stutzer and co-workers, 4×10^{-6} , for the coeff. of magnetization. The subject was studied by G. Grenet, and L. Pauling and M. L. Huggins.

The physical properties of marcasite.—The general mode of occurrence, and preparation of marcasite have been discussed in connection with pyrite; and there are, as in the case of pyrite, pseudomorphs after pyrrhotite, galena, copper pyrites, siderite, calcite, barytes, etc. The **colour** of marcasite is pale bronze-yellow, with a tinge of green; the colour deepens on exposure. The mineral readily tarnishes. The streak is greyish- or brownish-black. J. L. C. Schroeder van der Kolk¹⁷ said that the streak is greenish-grey. J. A. Hedvall discussed the changes in colour which occur on heating the mineral. Marcasite occurs in stalactitic forms with a radiating internal structure, having the exterior sometimes covered with projecting crystals. The stalactitic form may occur in layers with galena or sphalerite, or both, and this resembles schalenblende, hence it has been called *Schalenmarcasite*. Marcasite also occurs in globular, reniform, and other imitative shapes. The general appearance of marcasite has given rise to some special descriptive terms. For example, *radiated pyrites*—*Strahlkies*—occurs in radiating masses and in simple crystals; *combscomb pyrites*—*Kammkies*—occurs in aggregates of flattened, twinned crystals having crest-like forms; *spear pyrites*—*Speerkies*—occurs in twinned crystals with re-entering angles which have some resemblance to the head of a spear; *capillary pyrites*—*Zellkies*—occurs in cellular masses formed by the incrustation of crystals of other minerals that have disappeared, the marcasite is here usually mixed with pyrite; and *hepatic pyrites*—*Leberkies pyrites fuscus*—occurs massive in dull colours, and the term includes brown specimens of any pyrite altered more or less to limonite.

R. J. Haiiy, C. C. Leonhard, and J. A. H. Lucas showed that the **crystals** of marcasite, or *fer sulfure blanc*, are rhombic. J. J. Bernhardt, J. F. L. Hausmann, and F. Mohs also made observations on the rhombic crystals, although A. Gehmacher showed that some measurements agreed with the assumption that some crystals are monoclinic. The axial ratios of the rhombic crystals given by A. Sadebeck are: $a : b : c = 0.7662 : 1 : 1.2342$; V. M. Goldschmidt gave $0.7580 : 1 : 1.2122$; J. F. L. Hausmann, $0.75241 : 1 : 1.18473$; G. T. Prior, $0.7662 : 1 : 1.2342$; A. Gehmacher, and W. F. de Jong, $0.762256 : 1 : 1.216698$; and for the artificial crystals, E. T. Allen and co-workers gave $0.7646 : 1 : 1.2176$. The common habit of the crystals of marcasite is pyramidal and also tabular, parallel to the (001)-face; with the brachydomes and pinacoids deeply striated parallel to the (010)/(001)-edge. E. T. Allen and co-workers found that the artificial mineral has these faces similarly striated, and the pyramid and prism zones are even more prominently striated parallel to the base; the common habit of the artificial crystals is also tabular, and pyramidal. The crystals of marcasite show **twinning** about the (110)-plane, and the twinning is frequently repeated so as to produce, in some cases, stellate fivelings; twinning about the (101)-plane is less frequent, and the crystals then cross at angles approaching 60° . The twinning was discussed by C. Viola, F. Wallerant, and F. Schöndorf and E. Schroeder. E. T. Allen found that the artificial crystals occur twinned about the (110)-plane, and that they are tabular parallel to this plane, and elongated along the vertical axis, and the (101)- and (011)-domes are prominent. The artificial pyramidal crystals are developed more symmetrically than the tabular crystals, and they are less frequently twinned. The (101)- and (011)-domes are characteristic, and the striated prisms, (110), are usually prominent. The crystals of marcasite were described by M. J. Buerger, G. Flink, F. A. Bannister, N. Watitsch, C. A. Tenne, O. Luedecke, C. O. Trechmann, F. Sandberger, E. R. Smith and R. A. Schroeder, W. D. Johnston, G. Werner, P. Groth, A. Breithaupt, A. Frenzel, A. Stelzner, H. Traube, E. Thomson, F. Roemer, B. Kosmann, C. Hintze, A. Gehmacher, V. R. von Zepharovich, A. Koch, A. Brunlechner, G. Grattarola, A. d'Achiardi, G. la Valle, P. Tschirwinsky, A. Lacroix, R. P. Greg and W. G. Lettsom, J. H. Collins, P. von Jereméeff,

J. D. Dana, etc. The **cleavage** on the (110)-face is rather distinct, while that on the (011)-face appears only in traces. The corrosion figures were studied by H. Schneiderhöhn; and the microscopic structure of polished surfaces also, by F. N. Guild, and H. Schneiderhöhn. J. Königsberger distinguished the anisotropy of marcasite from the isotropy of pyrite. W. F. de Jong found that **X-radio-grams** of marcasite correspond with a lattice with $a=6.79$ Å., $b=4.45$ Å., and $c=5.42$ Å.—the values for mispickel being $a=6.44$ Å., $b=4.76$ Å., and $c=5.63$ Å.

FIG. 636.—The Arrangement of the Atoms in Crystals of Marcasite.

M. J. Buerger found that there are two FeS_2 -mols. per unit cell; and that the lattice dimensions are $a=3.37$ Å., $b=4.44$ Å., and $c=5.39$ Å. The paired sulphur atoms are 2.25 Å. apart; the unpaired sulphur atoms, 2.96 Å.; the iron atoms, 5.52 Å.; and the sulphur-iron atoms, 2.21 Å. The atoms in the (001)-, (100)-, and (010)-elevations are indicated in Fig. 636. N. Alsén observed the parameters: $a=3.35$ Å., $b=4.40$ Å., and $c=5.35$ Å., and his construction of the arrangement of the component atoms is indicated in Fig. 637. Observations were made by P. F. Kerr, by H. V. Anderson and K. G. Chesley, F. R. and K. R. van Horn, and by W. Jansen. M. L. Huggins discussed the structure of the space-lattice and assumed that the sulphur atoms occur in pairs, each sulphur atom being linked, by pairs of electrons, to one sulphur atom and four iron atoms, and each iron atom to six sulphur atoms.

C. F. Rammelsberg gave 4.865 to 4.900—best representative value 4.90—for the **specific gravity** of marcasite; V. Pöschl found 4.607 to 4.879; E. Madelung and R. Fuchs, 4.8487; H. N. Stokes, 4.880 to 4.891; F. Sandberger, 5.08; F. E. Neumann, 4.882; J. D. Dana, 4.678 to 4.847; A. Breithaupt, 4.601 to 4.879; G. Rose, 4.848; and C. Hintze, 4.65 to 4.88. F. Wöhler's value, 4.74, is too low. The best representative value is 4.88.

E. T. Allen gave 4.887 at 25° for the sp. gr. of artificial marcasite, and found that when the compound is heated to 610° for some time the sp. gr. rises to 4.911, corresponding with its transformation to pyrite, whose sp. gr. is >5.02 . The lower value observed is attributed to the porosity of the product. Other observations were made by C. Hatchett, A. P. Brown, G. Rose, E. Palla, A. A. Julien, N. Watitsch, E. T. Allen and co-workers, and E. Stutzer and co-workers. J. J. Saslawsky discussed the contraction which occurs when marcasite is formed from its elements. According to A. A. Julien, the **hardness** of marcasite on the macrodome face is 6, and on most of the other faces, 6.5. V. Pöschl found that for loads of 20 and 50 grms., the scratching hardness of marcasite is respectively 140.2 and 134.1 when the value for topaz, as

FIG. 637.—The Structure of Marcasite.

standard, is 1000; the corresponding values for pyrite are 182.2 and 199.1 respectively—*vide supra*, pyrite. O. Mügge observed no change in marcasite after it had been subjected to a press. of 20,000 atm. E. Madelung and R. Fuchs gave 0.0681 for the coeff. of **compressibility** in megabars per sq. cm.

The **specific heat** of marcasite may be a little greater than that of pyrite, though the available evidence is not sufficient to prove the statement. H. V. Regnault gave 0.1332 for the sp. ht. of marcasite, and A. Sella, 0.1460. As shown by E. T. Allen and co-workers, and E. Arbeiter, and indicated in connection with pyrite, marcasite slowly changes into pyrite by a monotropic or irreversible change; the speed of the reaction is accelerated by a rise of temp. and is attended by an evolution of heat—Fig. 638—and a decrease in the electrical resistance, but the

FIG. 638.—Action of Heat on the Electrical Conductivity of Marcasite.

J. Königsberger gave 3.5 for the **refractive index** of marcasite calculated from the electrical conductivity. C. Doelter found that marcasite is opaque to the **X-rays**. O. Rohde found that marcasite has a larger **photoelectric effect** than pyrrhotite, but a smaller one than pyrite.

F. Beijerinck, and R. G. Harvey found that the **electrical conductivity** of marcasite is much smaller than that of pyrite (*q.v.*). The values for the electrical conductivity of marcasite, in Siemen's units, taken parallel to each of the three axes, are indicated in Fig. 638. K. Baedeker gave 16.56 ohms for the **electric resistance** at 0° and parallel to the *b*-axis; and A. Wesely, 2.4 ohms at 0°. Observations were made by T. du Moncel. According to J. Königsberger and O. Reichenheim, the conductivity of marcasite is 500 times smaller than that of pyrite. A crystal of marcasite which had been heated to 400°, had the electrical resistance, *R*, parallel to the *b*-axis, at θ° , $R = 16.58(1 + 0.00264\theta + 0.00009\theta^2)e - 18500/(\theta + 273)273$. The values taken parallel to the *a*- and *c*-axis are nearly the same. The observed values parallel to the *b*-axis are:

θ	16°	65°	118°	150°	180°	220°	243°	-78°	-130°
<i>R</i>	10.25	4.68	2.75	2.20	1.81	1.50	1.30	242	>2600

The **thermoelectric force** of marcasite was studied by M. Kimura and co-workers, and T. du Moncel. R. C. Wells found the **electrode potential** of marcasite in *N*-KCl to be 0.72 volt; in *N*-H₂SO₄, 0.94 volt; in *N*-NaOH, -0.22 volt; and in *N*-Na₂S, -0.07 volt. A. Lipschitz and R. von Hasslinger observed that the **electromotive force** of marcasite is positive against a calomel electrode in sulphuric acid with and without ferrous and ferric sulphates; and V. H. Gottschalk and H. A. Buehler, that marcasite in distilled water against copper gives 0.37 volt. E. F. Smith observed that the sulphur of marcasite is completely oxidized when a suspension of the powdered mineral in molten potassium hydroxide is electrolyzed under conditions where about half the sulphur of pyrite is oxidized. K. Fischbeck studied the electrochemical reduction of marcasite; M. Padoa and B. Zanella, the electrolysis of soln. of ammonium or sodium chloride, and ammonium thiocyanate whereby the iron dissolves in the ferric state; and R. C. Wells, the anodic and

cathodic polarization of marcasite. F. Stutzer and co-workers found the **magnetic susceptibility** of marcasite to be 5.43×10^{-6} vol. unit. J. Huggett and G. Chaudron said that marcasite is non-magnetic and it undergoes oxidation in air at 400° .

A comparison of pyrite and marcasite.—A general comparison of the properties of pyrite and marcasite—summarized by A. A. Julien¹⁸ (with modifications) in Table XCIV—shows that the colour of pyrite is brass-yellow, that of marcasite is more grey. H. N. Stokes added that with suitable precautions against misleading tarnish colours, pyrite can be readily distinguished from marcasite by the colour, but it is sometimes impossible to draw any satisfactory conclusions from the colours of fine-grained concretions, or from specimens with rough surfaces. The crystals of pyrite are cubic; those of marcasite rhombic; the habit of pyrite is striated cubes or pentagonal dodecahedra, that of marcasite is tabular or pyramidal, usually fibrous and radiating. The fracture of pyrite is usually conchoidal, that of marcasite uneven and radiating. The streak of pyrite has usually a greenish tinge; that of marcasite, greyish. C. Frebold distinguished pyrite from marcasite by their X-radiograms. E. Grill treated both minerals with hydrogen peroxide, but pyrite alone gives a deposit of sulphur. The sp. gr. of pyrite is greater—representative values at 25° being 5.03 for pyrite and 4.88 for marcasite, but H. N. Stokes added that the attempt to calculate the proportions of marcasite and pyrite from the sp. gr. of the sample is illusive. Pyrite is slightly harder than marcasite; the electrical conductivity of pyrite is 500 times that of marcasite. Marcasite is more susceptible to atm. oxidation at ordinary temp. or when heated. Pyrite dissolves completely in nitric acid, whilst marcasite dissolves with the separation of sulphur.

L. Gedel, and R. Scheuer separated the different sulphides of iron by treatment with conc. hydrochloric acid. The powdered mixture is extracted with carbon disulphide to remove free sulphur; then treated with conc. acid whereby ferrous sulphide dissolves completely, whilst ferric sulphide dissolves with the separation of an equivalent of sulphur: $\text{Fe}_2\text{S}_3 + 4\text{HCl} = 2\text{FeCl}_2 + 2\text{H}_2\text{S} + \text{S}$. The sulphur is extracted by carbon disulphide, and calculated to ferric sulphide. The residual iron disulphide is dissolved by conc. nitric acid or aqua regia. The proportion of ferrous sulphide can be calculated from the total sulphur or total iron, and that present as Fe_2S_3 and FeS_2 . C. W. Dickson observed that whilst pyrrhotite is completely soluble in 10 per cent. nitric acid, magnetite is scarcely attacked.

According to H. N. Stokes, if the mineral is boiled with a soln. of iron-alum containing a gram of ferric iron, and 16 c.c. of 25 per cent. sulphuric acid per litre, the proportion of sulphur oxidized in the case of pyrite is 60.4 per cent. of the contained sulphur, whilst with marcasite only 18 per cent. is oxidized. The reaction was utilized by E. T. Allen and co-workers for finding the relative proportions of marcasite and pyrite in a sample of pyrites—*vide infra*. The chemical analysis of pyrites was described by E. T. Allen and J. Johnston, F. Chio, M. Ditrach, L. Gadais, E. Mengler, R. Müller, P. L. Robinson and co-workers, A. M. Smoot, G. Weyman, and E. Zintl and F. Schloffer.

The chemical properties of pyrite and marcasite.—H. Rose¹⁹ observed that pyrite dissociates at a lower temp. when it is heated in hydrogen than when it is heated simply in a closed vessel. No hydrogen sulphide was formed. H. Conder, and T. J. Drakeley, however, found that at a dull red-heat, hydrogen sulphide and ferrous sulphide are formed; whilst G. Gallo said that three stages can be detected in the reduction: (i) $2\text{FeS}_2 + \text{H}_2 = \text{Fe}_2\text{S}_3 + \text{H}_2\text{S}$, commencing at 228° to 230° ; (ii) $\text{Fe}_2\text{S}_3 + \text{H}_2 = 2\text{FeS} + \text{H}_2\text{S}$, commencing at 280° to 285° ; and (iii) $\text{FeS} + \text{H}_2 = \text{Fe} + \text{H}_2\text{S}$, commencing at 370° to 375° . No sulphur compound analogous to Fe_3O_4 was observed—*vide supra*, the preparation of ferrous sulphide. H. Conder discussed the “hydrogen roasting” of pyrites to recover sulphur and iron. When pyrite is heated in air, it furnishes sulphur dioxide, and ferrous sulphate, but at a higher temp., a basic ferric sulphate or ferric oxide is formed. Next to sulphur, pyrites is the most important material for the manufacture of

the sulphur dioxide required for the manufacture of sulphuric acid. For this purpose the pyrites is roasted in special ovens. If the pyrite be heated in a closed vessel with a limited supply of air, so that the pyrite is in excess, the products are sulphur dioxide and ferrous sulphate; and if the pyrite is heated in air to 100° , or ground dry in a mortar, these are the first products of the oxidation. P. Truchot represented the reactions involved in roasting pyrites by the equations: $\text{FeS}_2 + \text{O}_2 = \text{FeS} + \text{SO}_2$; $2\text{FeS} + 3\text{O}_2 = 2\text{FeO} + 2\text{SO}_2$; $2\text{FeO} + \text{O} = \text{Fe}_2\text{O}_3$; $2\text{SO}_2 + \text{O}_2 = 2\text{SO}_3$, and $2\text{FeO} + 2\text{SO}_3 = 2\text{FeSO}_4$, and at about 530° , $2\text{FeSO}_4 = \text{SO}_2 + \text{SO}_3 + \text{Fe}_2\text{O}_3$. In some cases, ferrosic oxide is formed: $\text{FeS}_2 + 10\text{Fe}_2\text{O}_3 + \text{O}_2 = 7\text{Fe}_3\text{O}_4 + 2\text{SO}_2$.

TABLE XCIV.—COMPARISON OF PYRRHOTITE, MARCASITE, AND PYRITE.

	Pyrrhotite	Marcasite	Pyrite
Composition.	Fe_8S_6 to $\text{Fe}_{16}\text{S}_{17}$, and commonly nickeliferous	FeS_2	FeS_2
Hardness with steel	3.5-4.5	6.0-6.5 Striking fire imperfectly, with strong sulphurous odour	6.0-7.0 Striking fire readily with weak sulphurous odour
Specific gravity	4.4-4.68 (4.67)	4.68-4.85 (4.88)	4.74-5.19 (5.03)
Colour.	Bronze - yellow to steel to black-brown	Greyish-white to bronze-yellow	Golden to pale brass-yellow
Streak.	Greyish-black	Greenish - grey to brownish-black	Brownish-black
Fracture	Uneven	Uneven, radiating	Conchoidal to uneven
Grains.	Compact and magnetic	Columnar structure	Often fibrous and radial
Crystals	Rare: hexagonal, generally tabular, and magnetic	Common: Orthorhombic, often in striated twins, toothlike or crested forms, etc.	Abundant: isometric cubes, pyritohedra, octahedra, etc.
Ignition in closed tube	Unchanged	Yielding a sublimate of sulphur and a magnetic residue	(Like marcasite)
Heating to 450°	Stable	Stable	Converted to pyrite
Specific heat	0.1500	0.1332	0.1306
Nitric acid	Insoluble	Soluble with separation of sulphur	(Like marcasite)
Hydrochloric acid.	Soluble with separation of sulphur and hydrogen sulphide	Insoluble	Insoluble
Alteration	Iridescent tarnish	Iridescent, often efflorescent	Iridescent, efflorescent, or hepatic colour

The formation of soluble sulphate after 6 hrs'. roasting amounted to 1.0108; after 12 hrs', 0.4816; and after 18 hrs', 0.0994 per cent. This shows that the sulphate is formed early in the operation of roasting pyrite, and decomposes in the later stages. If the supply of air is very limited, and if the temp. is high enough, some sulphur may distil off as well—*vide supra*, the action of heat on pyrite—and in large pieces, sulphur may distil from the interior and burn at the surface. In either case pyrrhotite is formed to which A. Scheurer-Kestner and A. Rosenstiehl gave the formula FeS ; T. Sidot, Fe_3S_4 ; and H. V. Regnault, Fe_5S_6 —*vide supra*. If the temp. rises rapidly, the ferrous sulphide may fuse before the volatiles are evolved, and leave a vitreous, vesicular slag. The air which has access to the surface of the pyrite forms a film of ferric oxide, which, according to A. Lemoine, oxidizes the ferrous sulphide lower down, and the reduced ferric oxide is re-oxidized by the air.

The reaction was studied by T. L. Phipson, T. Gibb, F. Warlimont, F. Bode, E. Richters, E. Knop, M. Fortmann, B. G. Bredberg, J. L. Proust, M. Bräuning, F. C. Thompson and N. Tilling, J. Milbauer and J. Tucek, W. Eitel, H. Saito, B. Neumann and co-workers, J. Jelinek, H. W. Nelson and co-workers, H. E. Woisen, and I. N. Kuzminikh. P. Truchot gave 440° to 450° for the temp. at which the oxidation of the sulphur in pyrite begins; A. W. Warwick said 290° – 315° , and the heat of the oxidation may raise the temp. to 455° . J. W. Mellor compared the percentage amounts of the contained sulphur in pyrite and marcasite after heating 2 to 3 hrs. at different temp. in a current of air, and the results are summarized in Fig. 639. They show that the oxidation of marcasite sets in before that of pyrite, but thereafter they follow along similar lines. The subject was studied by F. G. Jackson. A. W. Warwick measured the result on a rising temp. and found that a sample with 15.2 per cent. of sulphur, after heating :

Time	0	1	2	3	4	8	18 hrs.
Temperature . .	150°	203°	203°	203°	321°	357°	400°
Sulphur	15.2	13.2	10.1	7.4	5.6	2.1	0.11 per cent.

FIG. 639.—The Oxidation of Pyrite and Marcasite at Different Temperatures in Air.

There was no evidence of the formation of an intermediate ferrous sulphide, and he represented the reaction by the equations: $\text{FeS}_2 + 5\text{O} = \text{FeO} + 2\text{SO}_2$; $2\text{SO}_2 + \text{O}_2 = 2\text{SO}_3$; $\text{SO}_3 + \text{FeO} = \text{FeSO}_4$; $\text{FeSO}_4 + \text{FeO} = \text{Fe}_2\text{O}_3 + \text{SO}_2$; the initial and end states being $4\text{FeS}_2 + 11\text{O}_2 = 2\text{Fe}_2\text{O}_3 + 8\text{SO}_2$. The roasting of pyrites—pyrite and marcasite—for sulphur dioxide (*q.v.*) has played an important part in the manufacture of sulphuric acid. A. Wurm showed that in some cases sulphur may be formed by the oxidation: $\text{FeS}_2 + 7\text{O} + \text{H}_2\text{O} = \text{FeSO}_4 + \text{H}_2\text{SO}_4$; $6\text{FeSO}_4 + 3\text{O} + 3\text{H}_2\text{O} = 2\text{Fe}_2(\text{SO}_4)_3 + 2\text{Fe}(\text{OH})_3$; $\text{FeS}_2 + \text{H}_2\text{SO}_4 = \text{FeSO}_4 + \text{H}_2\text{S} + \text{S}$; and $\text{FeS}_2 + \text{Fe}_2(\text{SO}_4)_3 = 3\text{FeSO}_4 + 2\text{S}$. The formation of sulphur in the weathering of pyrites was discussed by E. Dittler. The sparks obtained when pyrites is struck with steel, were attributed by A. Johnsen to the heat developed by the friction oxidizing the particles and the heat so developed raised them to a red-heat. G. F. Hüttig and P. Lürmann showed that the reaction between pyrites and oxygen is reversible, that the final product is a solid soln. of oxide and sulphide; and that these two react on cooling to form ferrous sulphate: $4\text{Fe}_2\text{O}_3 + \text{FeS} = \text{FeSO}_4 + 8\text{FeO}$. The composition of the solid soln. is given by $n^{-1} = 13.0 - 6.66 \log (p_{\text{SO}_2}/p_{\text{O}_2})$, where n^{-1} is the Fe:S ratio. E. F. Smith discussed the electrolytic oxidation of pyrites in molten alkali hydroxide—*vide supra*.

According to J. J. Berzelius, many samples of pyrites are converted into hydrated ferric oxide and sulphuric acid when exposed to moist air, and marcasite, indeed, often becomes quickly covered with an efflorescence of ferrous sulphate. J. J. Berzelius thought that the fact that the efflorescence shows itself only irregularly on a mass of marcasite, shows that ferrous sulphide is present as well as iron disulphide. The two form a galvanic couple with the disulphide forming the negative pole. The disulphide, he added, remains unaltered, but is shattered by the expansive force of the growing crystals of ferrous sulphate. When the soluble salt is washed out by water, there is no evidence of the formation of free sulphur. L. Gmelin reported free sulphur in the products of the efflorescence of marcasite from Schriesheim. J. J. Berzelius found a sample which effloresced in humid air in 12 hrs., expanded ten-fold in 4 days. Iron pyrites imperfectly roasted

so that only a part of the disulphide is converted to monosulphide, shows a marked tendency to efflorescence.

Many examples have been quoted—by J. S. Newberry, J. Gray, A. de Selle, P. A. Dufrénoy, G. F. Becker, T. Egleston, T. Scheerer, A. Girard and H. Morin, and C. Méne—but explanations are not so easy to find. J. F. Henckel attributed the ready weathering to the presence of impurities, density, texture, etc., as he said *unius rei plures possunt esse causæ*; A. G. Werner also suspected that the presence of arsenic might favour decomposition; J. J. Berzelius, manganese, etc.; F. Stromeyer, free sulphur; and C. Hatchett, the presence of “a small portion of oxygen being previously combined with a part, or with the general mass of sulphur, at the time of the original formation of these substances, so that the state of the sulphur is tending to that of oxide, and thus a further addition of oxygen becomes facilitated.” J. L. Proust considered that pyrites with the smallest proportion of sulphur are most liable to decomposition, but C. Hatchett said that this is so far from being in accord with facts, that “I might be induced to adopt the contrary opinion.” J. J. Berzelius considered that the presence of pyrrhotite in pyrites favoured the weathering of pyrites, but F. Köhler considered that his analyses did not agree. Later on, J. J. Berzelius said that it seems “highly probable that the falling asunder of ordinary pyrites arises from the electrochemical action of electronegative bisulphuret which is here and there mixed with it in small particles.” F. Senft favoured this hypothesis. A. Girard and H. Morin attributed the phenomenon to “the enclosure of a clay easily attacked either by atmospheric agents, or by water, may well be a ready cause of their alteration.” J. Fournet said that “a spontaneous tendency to dimorphism produces the disintegration of the minerals, and this is followed by chemical action.” He asked: May not prismatic marcasite be simply an unstable form of pyrites, pyrite, the stable form? just as prismatic aragonite is the unstable form of calcium carbonate, and rhombohedral calcite the stable form. J. Nicol, and J. P. Kimball attributed the difference in the tendency to decomposition on exposure to the atmosphere, to some peculiarity in the state of molecular aggregation, or to molecular differences arising from crystalline structure. A. A. Julien found that the varieties of pyrites which weather easiest are mixtures of marcasite and pyrite in intimate association. H. Schneiderhöhn attributed the differences to the presence of colloidal disulphide which is very susceptible to attack; and F. Zirkel found pyrite from sedimentary deposits weathers more readily than that from crystallized rocks. The subject was discussed by H. Willert. According to U. Panichi, if the (111)-faces of pyrite predominate, the crystals succumb to attack far more readily than if the (210)-faces are dominant. F. Katzer attributed the resistance of a pyrite from Bornia to the compact nature of the surfaces of the crystals. F. Carmichael observed that powdered marcasite agitated for 13 days with water and oxygen, suffers 0.29 per cent. oxidation, and pyrite, 0.02 per cent.

J. J. Berzelius added that since the efflorescence of pyrites is attended by the evolution of heat, the spontaneous inflammation of pyritiferous coals may be explained when the coals are heaped up in masses—within or without the mine—and exposed to humid air. H. Macpherson and co-workers showed that not only is the heat of oxidation of importance, but that the disintegration produced by the volume changes on oxidation, noted by J. J. Berzelius, facilitates the access of air to the coal itself, and that this favours rapid oxidation and ignition. The drainage water from some mines contains ferrous sulphate derived from the oxidation of pyrites. Advantage is taken of the reaction in the old method of preparing ferrous sulphate by exposing pyrites in heaps in moist air, and collecting the drainage water in tanks for evaporation. The manufacture of fuming sulphuric acid (*q.v.*) near Nordhausen involves the oxidation of the pyritiferous slates to form the vitriol stone—a mixture of ferrous and ferric sulphates—which is subjected to dry distillation for the acid. W. H. Emmons said that the heat of oxidation is enough to raise the temp. of average mine-water by 12.7°.

E. F. Smith found that a current which would completely oxidize the sulphur in marcasite in a given time would oxidize less than half of the sulphur in pyrite in the same time. This remaining sulphur was held very tenaciously, though the mineral was subjected to more powerful currents and longer-continued action than in the case of marcasite or pyrrhotite. Finally, by adding an equal quantity of cupric oxide, and using a more powerful current, all of the contained sulphur was oxidized. Previous to the addition of cupric oxide but 21 or 22 per cent. of the sulphur was oxidized.

The first sign of weathering is the dulling of the surface which then becomes matt, and later brown. When the grains of pyrites have succumbed to weathering influences, there is a brownish film of limonite or goethite admixed with a little yellowish-green free sulphur, and ferric and ferrous sulphates. This subject was discussed by W. Mietzschke, M. Rolland, F. von Kobell, F. Senft, O. J. Heinrich, H. Bauerman, J. Roth, J. R. Blum, and G. Rose. S. H. Emmens represented the order in which sulphides oxidize, beginning with the one most easily attacked: marcasite, millerite, chalcocite, galena, and zinc blende; C. R. van Hise gave: Fe, Cu, Zn, Pb, and Ag sulphides; W. H. Emmons gave: sphalerite, chalcocite, pyrrhotite, chalcopyrite, pyrite, galena, and enargite; whilst for the attack with 0.057N-H₂SO₄, R. C. Wells gave: pyrrhotite, sphalerite, galena, chalcopyrite, and pyrite; and V. H. Gottschalk and H. A. Buehler measured the e.m.f. of various mineral sulphides in distilled water against copper—*vide supra*. F. Köhler showed that the crust on weathered marcasite may contain a comparatively large proportion of ferrous sulphate, and this crystallizing in the minute pores and fissures forms an efflorescence, and, as indicated above, disintegrates the grains more completely. E. Arbeiter, and H. N. Stokes, in agreement with general observations, have shown that marcasite weathers much more rapidly than pyrite, and that some specimens of pyrite are remarkably resistant to weathering influences. The formation of basic sulphates, sulphates, and sulphuric acid in the early stages of the oxidation of pyrites, and the simultaneous formation of ferrous sulphide was discussed by L. Benedek, W. A. Caldecott, S. H. Emmens, J. Loczka, T. Scheerer, and C. Winkler. E. Dittler observed no sulphate formation in a current of carbon dioxide. T. F. Winmill observed no formation of ferric sulphate. E. T. Allen and co-workers found that in a sealed tube, filled with air, ferrous and ferric sulphates and sulphur dioxide are formed at 100°; a similar reaction occurs if pyrites is triturated in air, and in ordinary air at 75°, some hydroxide is formed. The stages in the transformation of pyrites to limonite are: $\text{FeS}_2 \rightarrow \text{FeSO}_4 \rightarrow \text{Fe}_2(\text{SO}_4)_3 \rightarrow \text{Fe}_2\text{O}_3 \cdot n\text{H}_2\text{O}$. The reactions have been symbolized: $2\text{FeS}_2 + 7\text{O}_2 + 2\text{H}_2\text{O} = 2\text{FeSO}_4 + 2\text{H}_2\text{SO}_4$; $12\text{FeSO}_4 + 3\text{O}_2 + 6\text{H}_2\text{O} = 4\text{Fe}_2(\text{SO}_4)_3 + 4\text{Fe}(\text{OH})_3$. The ferrous and ferric sulphates may be in part washed away by currents of water, and if calcium, magnesium, barium, or strontium compounds are in the track of the underground current of water, crystals of sulphates of these bases may be formed—*e.g.*, epsomite, selenite, barytes, etc. J. W. Evans discussed this subject and represented the reaction with calcium carbonate: $4\text{FeS}_2 + 15\text{O}_2 + 3\text{H}_2\text{O} + 8\text{CaCO}_3 = 2\text{Fe}_2\text{O}_3 \cdot 3\text{H}_2\text{O} + 8\text{CaSO}_4 + 8\text{CO}_2$. The ferric sulphate in these waters is an active oxidizing agent, and acts as an oxygen carrier to surrounding ores. It acts on pyrite: $\text{Fe}_2(\text{SO}_4)_3 + \text{FeS}_2 = 3\text{FeSO}_4 + 2\text{S}$, and the nascent sulphur is oxidized to sulphurous and finally sulphuric acid. This subject was discussed by H. Schneiderhöhn, and F. C. Thompson and N. Tilling. The limonite may appear as a residual deposit like beds of laterite; as a so-called gossan-cap or a mass of porous limonite extending to a considerable depth in an outcrop of pyrite or chalcopyrite; and as pseudomorphs of limonite after pyrite. H. M. Chance, and S. H. Emmens discussed the pyritic origin of iron ores; G. M. Schwartz, and W. A. Tarr, the weathering of pyritic ores to limonite. H. Laubmann, P. W. Jeremejeff, E. Hussak, A. Lacroix, E. Geinitz, E. Döll, H. B. North, and J. R. Blum observed pseudomorphs of limonite after pyrite, or marcasite; J. R. Blum, goethite; G. C. Hoffmann, and J. R. Blum, hæmatite; A. Reuss, galena; J. Holdsworth, quartz; F. P. Menzel, bornite; H. A. Miers,

chalcocite ; F. Kretschmer, stilpnomelane ; and W. Eitel, R. Brauns, and O. Mügge, pyrrhotite. S. Hilpert said that the oxidation may go to ferrosic oxide ; and A. Lacroix to melanterite, $\text{FeSO}_4 \cdot 7\text{H}_2\text{O}$, if the oxidation has been rapid. A. R. Whitman represented the sequence in the formation of china-clay and chlorite from felspar by metasomatic replacement by the equations : (i) $2\text{FeS}_2 + 2\text{H}_2\text{O} + 7\text{O}_2 = 2\text{Fe}(\text{HSO}_4)_2$; (ii) $15\text{Fe}(\text{HSO}_4)_2 + \text{FeS}_2 = 2\text{FeS}_2 + 7\text{Fe}_2(\text{SO}_4)_3 + 7\text{H}_2\text{SO}_4 + 8\text{H}_2\text{O}$; (iii) $4\text{KAlSi}_3\text{O}_8 + 3\text{H}_2\text{SO}_4 + 7\text{H}_2\text{O} = \text{H}_4\text{Al}_2\text{Si}_2\text{O}_9 + \text{Al}_2(\text{SO}_4)_3 + 2\text{K}_2\text{SiO}_3 + 8\text{H}_2\text{SiO}_3$; and (iv) $\text{H}_4\text{Al}_2\text{Si}_2\text{O}_9 + 3\text{H}_2\text{SO}_4 = \text{Al}_2(\text{SO}_4)_3 + 2\text{H}_2\text{SiO}_3 + 3\text{H}_2\text{O}$. According to A. Matsubara, natural sulphide ores convert the H^+ -ions of ground water into HS^- -ions with a lower surface potential.

O. Weigel²⁰ observed that **water** dissolves 0.044889 mol of pyrite per litre, and 0.044084 mol of artificial pyrite ; E. Dittler found the solubility of pyrite in water is small, but increases if oxygen is passed through the liquid ; C. Doelter observed that at 80° , 0.10 grm. of pyrite dissolves in 100 grms. of distilled water ; and 0.037 grm. of marcasite dissolves in 100 grms. of water. Observations were also made by J. W. Evans, and E. Dittler. A. N. Winchell noted that by passing air through water with 300 grms. of finely-powdered pyrite in suspension for 10 months, an appreciable quantity of ferric sulphate and sulphuric acid passed into soln. F. F. Grout obtained similar results ; and V. A. Gottschalk and H. A. Buehler observed a more rapid attack. J. W. Gruner found that when 15 grms. of pyrite were treated with about 500 c.c. of peat water for 77 days, 23 parts of Fe per million passed into soln. ; and a trace only dissolved in 30 days. J. W. Evans showed that with frequently-renewed water, powdered pyrite is slowly decomposed forming soluble iron sulphate ; and that aerated water charged with calcium carbonate slowly converts pyrite into limonite as indicated above. C. A. Burghardt found that water in a sealed tube at 120° decomposes pyrite forming sulphuric acid, ferrous and ferric sulphates, and hydrogen sulphide. C. F. Tolman and J. D. Clark observed that when pyrite is kept with water in a sealed tube at 41° for 3 months, some hydrogen sulphide is formed. S. F. Emmons observed that water with dissolved hydrogen sulphide or alkali sulphide dissolves some pyrite ; and G. F. Becker found that at room temp., one part of pyrite is soluble in 1800 parts of 1.5 molar sulphide soln. H. Freundlich and co-workers studied the adsorption of water. H. Freeman also observed the solubility of iron sulphide in soln. of alkali sulphide. F. Foreman observed that in a sealed tube artificial pyrite in contact with water at 100° dissolved 0.64 part of Fe per million, and at 250° , 0.72 part per million. With natural pyrite :

SOLVENT	DISSOLVED	100°	150°	250°	320°		
Water	Fe	0.11	0.07	0.04	0.24	parts per million	
	Fe eq. H_2S	0.00	0.00	19.8	51.5	"	"
0.1N- NaHCO_3	Fe	0.02	0.04	0.07	0.24	"	"
	Fe eq. H_2S	0.00	10.05	19.50	—	"	"
0.1N- Na_2S	Fe	0.00	0.00	0.00	0.04	"	"
	Fe eq. H_2S	—	—	8.65	—	"	"

H. N. Stokes observed that by circulating alkaline water about pyrite and marcasite, hæmatite and hydrated ferric oxide are formed, and the sulphur forms alkali sulphide and thiosulphate. C. A. Burghardt observed that powdered pyrite and water in a sealed tube at 120° form hydrogen sulphide, sulphuric acid, ferric and ferrous sulphates, and a little hydrated ferric oxide. L. Benedek found that steam at 300° to 400° converts pyrite into ferrous oxide and hydrogen sulphide. E. T. Allen and co-workers added that pyrrhotite is an intermediate state in the reaction. E. Grünert represented the action of steam on pyrite by the equations : $\text{FeS}_2 \rightleftharpoons \text{FeS} + \text{S}$; $6\text{S} + 4\text{H}_2\text{O} \rightleftharpoons 4\text{H}_2\text{S} + 2\text{SO}_2$; $\text{SO}_3'' + \text{S} = \text{S}_2\text{O}_3''$; $\text{FeS} + \text{H}_2\text{O} = \text{H}_2\text{S} + \text{FeO}$; and $3\text{FeO} + \text{H}_2\text{O} = \text{Fe}_3\text{O}_4 + \text{H}_2$. V. H. Gottschalk and H. A. Buehler discussed the relative speeds of oxidation of pyrite and marcasite under these conditions.

The reaction was studied by F. C. Thompson and N. Tilling. A. F. Taggart made experiments on the flotation of pyrite; E. Arbeiter found that **hydrogen dioxide** in 10 per cent. soln. with a little hydrochloric acid acts on powdered pyrite more readily than on marcasite. P. Ozegoff observed that both minerals are completely decomposed by 30 per cent. hydrogen dioxide; and E. Grill observed that with pyrite alone is there a separation of sulphur.

H. Moissan observed that **fluorine** does not attack pyrite in the cold, but at about 200° there is a violent attack. L. E. Rivot and co-workers found that when treated with alkali-lye through which **chlorine** is rapidly passed, finely-divided pyrite is completely decomposed. W. Kangro and R. Flügge found that at 900° all the iron was removed from pyrite in 30 minutes, and the distillate contained ferric chloride and sulphur monochloride. A. A. Julien found that **bromine** vapour at ordinary temp. attacks pyrite less rapidly than marcasite; and that the attack with bromine water is fairly rapid. J. Lemberg observed that a soln. of bromine in alkali-lye gradually decomposes pyrite. W. S. Allen and H. B. Bishop opened up the powdered mineral for analysis by shaking it with a soln. of bromine in carbon tetrachloride. H. Wurtz observed that, unlike pyrrhotite, pyrite is not dissolved by a freshly-prepared soln. of iodine, and E. Wilke-Dörfurt and E. A. Wolf found that pyrite is decomposed by heating it in the vapour of **iodine trichloride**. G. Gore, and E. Zalinsky observed that pyrite is insoluble in **hydrofluoric acid**. According to A. P. Brown, when dried **hydrogen chloride** is passed over pyrite and marcasite for an hour at 210°, the result is not very marked, but by raising the temp., the differences in the rates of attack on the two minerals is more marked. The percentage amounts of sulphur lost in the different cases were:

	15°	310°	325°	Red-heat
Pyrite	0.93-0.94	10.73	17.13	46.47
Marcasite	0.59-0.77	7.19	10.70	—

Pyrite is not easily attacked by dil. **hydrochloric acid**. A. P. Brown said that the cold or hot, conc. or dil. hydrochloric acid attacks the mineral very slowly; when pyrite was treated for an hour with the boiling conc. acid, of sp. gr. 1.2, only 2.56 out of 46.67 per cent. of iron passed into soln. Similar results were obtained with marcasite, and in both cases no evolution of hydrogen sulphide was observed. E. T. Allen and co-workers, and E. Weinschenk said that pyrite and marcasite are almost insoluble in hot, conc. hydrochloric acid, but V. Rodt observed that in the presence of strong reducing agents, like stannous chloride, pyrite, and particularly marcasite, are dissolved by the warm acid. H. St. C. Deville found that pyrite is converted by **hypochlorous acid** into iron sulphate. G. Spezia observed that an aq. soln. of **potassium chlorate**, at 15° to 16° for 21 hrs., oxidized some pyrite to sulphate.

E. E. and I. W. Wark studied the effect of sulpho-compounds on the flotation of pyrite. E. F. Smith found that pyrite and marcasite are not dissolved by cold **sulphur monochloride**, but at 140°, decomposition is complete, and ferric chloride is formed; H. B. North and C. B. Conover found that the reaction is complete in a sealed tube at 319°. H. Danneel and F. Schlottmann noted that the sulphide is attacked by **sulphuryl chloride**. According to A. Terreil, a 10 per cent. soln. of **alkali sulphide** attacks marcasite slowly, but not pyrite—*vide supra*. G. E. Becker also found that pyrite is far less readily attacked than marcasite by a soln. of sodium sulphide, or of hydrosulphide. C. Doelter observed that marcasite is more readily dissolved than pyrite by a soln. of sodium sulphide. The attack is favoured by raising the temp. The actions of sodium sulphide and hydrosulphide were studied by R. E. Stevens; pyrrhotite is formed. A. M. Gaudin and W. D. Wilkinson studied the action of dioxanthogens. R. F. Bacon treated iron sulphides with **sulphur dioxide** so as to liberate sulphur and produce iron oxide. L. Wöhler and co-workers, and the Rhenania Verein Chemischer Fabriken represented the reaction: $3\text{FeS}_2 + 2\text{SO}_2 = \text{Fe}_3\text{O}_4 + 8\text{S}$. J. Milbauer and J. Tucek observed

that ferrous sulphate is formed as an intermediate product particularly about 600°. The action of **sodium sulphite** was studied by R. E. Stevens, and represented by the equation: $\text{FeS}_2 + \text{Na}_2\text{SO}_3 = \text{Na}_2\text{S}_2\text{O}_3 + \text{FeS}$. Pyrites is but slowly affected by treatment with dil. **sulphuric acid**, and A. P. Brown, E. T. Allen and co-workers, and E. Divers and T. Shimidzu found that boiling, conc. sulphuric acid slowly decomposes both minerals with the evolution of sulphur dioxide, the formation of ferric sulphate, and the separation of sulphur. With pyrite during 1 hr.'s. action, 14.81 per cent. of iron dissolved, and with marcasite, 12.77 per cent. R. C. Wells found that the sulphides are attacked by 0.057N- H_2SO_4 in the order: pyrrhotite, sphalerite, galena, chalcopyrite, and pyrite. V. Lenher found that **selenium oxydichloride** attacks pyrite slowly in the cold, and vigorously when heated forming sulphur dioxide, and selenium monochloride.

A. P. Brown found that powdered pyrite gave no appreciable loss when heated to 325° in an atm. of **nitrogen**; and that when the powdered mineral is heated at 335°, in the vapour of **ammonium chloride**, a sublimate of ammonium sulphide is formed, and the amounts of sulphur lost by pyrite and marcasite in about 25 minutes, were respectively 7.06, and 9.50 per cent. Pyrite and marcasite are attacked by **nitric acid**, and by **aqua regia**, yielding a ferric salt, sulphuric acid, and sulphur. The reaction with nitric acid was studied by E. T. Allen and co-workers. H. B. Yardley observed that the sulphur is oxidized to sulphuric acid, and this more rapidly at 100° than at a higher temp. G. Kingsley found that with 5 per cent. nitric acid, no sulphate is formed at 75°, but only nitrate and sulphur. According to G. J. Brush and S. L. Penfield, when the finely-powdered minerals are treated with conc. nitric acid under the same conditions, pyrite dissolves completely, whilst marcasite leaves a residue of sulphur. A common method of opening pyrites for analysis, is to digest it with boiling aqua regia made by mixing 1 part of fuming hydrochloric acid with 3 or 4 parts of nitric acid of sp. gr. 1.36 to 1.40. According to G. Chaudron and G. Juge-Boirard, during the dissolution of pyrites in nitric acid or aqua regia, there is always a separation of free sulphur, in the case of marcasite or pyrites containing other sulphides, if the temp. exceeds 60°. If the acid is allowed to act at room temp., there is no separation of sulphur, but the time required for the dissolution is much longer. H. Rose observed that when pyrites is heated in **phosphine**, the reaction can be symbolized: $3\text{FeS}_2 + 4\text{PH}_3 = \text{Fe}_3\text{P}_4 + 6\text{H}_2\text{S}$. R. F. Weinland and L. Storz found that when powdered pyrite is heated many days with a soln. of **sodium arsenite**, some sulphur is formed—the reaction proceeds farther with marcasite. According to G. W. Plummer, when pyrites is heated to 250° with **arsenic trichloride** in a sealed tube, a colloidal soln. of arsenic, not arsenic sulphide, is formed; and when heated with an excess of **bismuth trichloride** in an atm. of carbon dioxide, decomposition is complete in about 5 minutes, and with both pyrite and marcasite, all the iron is in the ferrous state; the sulphur forms some monochloride, and about 91 per cent. appears as bismuth sulphide.

According to H. Rose, when pyrites is heated with **carbon**, carbon disulphide is formed; but A. Murlot, and T. J. Drakeley observed that at 500°, in an atm. of carbon dioxide, the sulphur is given off as hydrogen sulphide. According to E. Grünert, the reaction in an atm. of steam furnishes the phases which appear in the reactions between steam and pyrite, and between steam and carbon. The hydrolytic action on sulphur results in the formation of sulphur dioxide, which is reduced by the carbon. The desulphurization of the pyrites by carbon proceeds better in the presence of steam than in dry nitrogen, in the latter case, some sulphur is probably adsorbed by the carbon. F. C. Thompson and N. Tilling represented the reaction with **carbon monoxide** by $\text{FeS}_2 + \text{CO} = \text{FeS} + \text{COS}$. W. Thörner represented the reaction with **carbon dioxide** by the equation: $\text{FeS}_2 + 2\text{CO}_2 + 2\text{H}_2\text{O} = \text{S} + \text{H}_2\text{S} + \text{Fe}(\text{HCO}_3)_2$. The reaction was studied by F. C. Thompson and N. Tilling, and N. D. Costeanu. T. J. Drakeley, and L. Benedek found that dry carbon dioxide does not act at 500°, but the moist gas results in the formation of hydrogen sulphide; N. D. Costeanu observed that at 1000°, the pyrite decomposes

into ferrous sulphide and sulphur, and that the ferrous sulphide reacts with the carbon dioxide to produce carbon monoxide, sulphur, and ferrous oxide; at 1100° , ferric oxide takes the place of ferrous oxide. G. W. Plummer, and K. B. Rogers found that pyrites is readily decomposed when it is heated to 250° in the vapour of carbon tetrachloride. M. Berthelot said that **ether** in the presence of air extracts some sulphur from pyrites. According to H. C. Bolton, "three specimens of pyrite, with **citric acid** for 12 hrs. in the cold, gave no traces of gas, and three of pyrrhotite liberated it in the cold, and freely on boiling. All the specimens were decomposed by dil. hydrochloric acid excepting one sample of pyrite." By the prolonged contact of pyrite with a conc. soln. of citric acid, at 15° to 22° , there was evidence of decomposition in 8 days, and in a month, the soln. had acquired a reddish colour, and reacted for iron and sulphuric acid. Finely-powdered pyrite is quickly attacked by a mixture of potassium nitrate and citric acid in the cold, or by a boiling mixture of potassium nitrate or chlorate and citric acid. Parallel results were obtained with **tartaric acid** and potassium chlorate; and with **oxalic acid** and potassium nitrate. T. G. Pearson and P. L. Robinson found that, unlike ferrous and ferric sulphides, pyrite and marcasite are insoluble in soln. of **potassium cyanide**. E. Alberts studied the decomposition of pyrite when heated in the vapour of **carbon tetrachloride**. A. J. Scarlett and co-workers studied the emulsification of **benzene** by pyrites.

J. Struever observed that when pyrite is laid on **copper** foil, the metal is slowly blackened, and rapidly so with marcasite; similar results were obtained with **silver**. H. Ditz observed that a mixture of **aluminium** and pyrite furnishes 50 per cent. of the iron as metal when treated as in the thermite process; the remaining iron forms a slag of $\text{Al}_2\text{S}_3 \cdot \text{FeS}$.

J. A. Smythe found that when pyrite is treated with molten **potassium hydroxide**, at 150° , an intense blood-red colour is developed, which, when a little water is added, changes to pale green. The soln. contains some thiosulphate. R. E. Stevens represented the action of **sodium hydroxide** by the equation: $8\text{FeS}_2 + 30\text{NaOH} = 4\text{Fe}_2\text{O}_3 + 14\text{Na}_2\text{S} + \text{Na}_2\text{S}_2\text{O}_3 + 15\text{H}_2\text{O}$. In opening up pyrites for analysis, besides aqua regia or nitric acid, with or without bromine, H. C. Moore, K. List, and S. W. Parr recommend fusion with **sodium dioxide**; A. H. Low, treatment with a mixture of potassium hydrosulphate, tartaric acid, and sulphuric acid; O. Binder, fusion with a mixture of sodium carbonate and potassium nitrate; and W. C. Ebaugh and C. B. Sprague, fusion with a mixture of sodium carbonate and zinc oxide. According to G. Tammann and G. Bätz, the break in the heating curve of pyrites at 684° does not occur if calcium oxide be present; the liberated sulphur combines with the lime to form calcium sulphate and sulphide. A mixture of pyrites and lime is only slightly reduced when heated with wood charcoal. By the interaction of lime and pyrites a difficultly-reducible calcium iron oxysulphide is formed, and only a small quantity of ferrous oxide. P. Berthier found that when pyrites is heated with **lead oxide**, the mixture fuses and gives off sulphur dioxide; it requires 50 parts of lead oxide to 1 part of pyrites to expel all the sulphur. When 6 parts of lead oxide are used, two layers are produced—a lower layer of lead sulphide, and an upper layer of a mixture of lead and ferrous sulphides and oxides. F. Martin and O. Fuchs represented the reaction with **ferric oxide** by the equation: $2\text{Fe}_2\text{O}_3 + 7\text{FeS}_2 = 11\text{FeS} + 3\text{SO}_2$.

C. Doelter observed that with a 10 per cent. soln. of **sodium carbonate**, 7.08 per cent. dissolved from pyrite and 4.17 per cent. from marcasite; and H. N. Stokes found that if pyrite or marcasite be heated in a sealed tube with **sodium hydrocarbonate** at 185° , alkali sulphide and thiosulphate, and ferric oxide are formed. The reaction is in part reversible. If other carbonates of the heavy metals be present, the yield of thiosulphate is increased. The reaction of pyrite or marcasite with **copper carbonate** in the presence of alkali carbonate or hydrocarbonate, in a sealed tube at 160° to 180° for 14 hrs., is symbolized: $2\text{FeS}_2 + 6\text{CuCO}_3 + 2\text{KHCO}_3 = 3\text{Cu}_2\text{S} + \text{Fe}_2\text{O}_3 + \text{K}_2\text{SO}_4 + 8\text{CO}_2 + \text{H}_2\text{O}$. A similar result was obtained with **silver**

carbonate. J. W. Evans found that with water containing **calcium carbonate** in soln., pyrite and marcasite furnish hydrated ferric oxide. H. N. Stokes observed that with **zinc carbonate**, $8\text{FeS}_2 + 14\text{ZnCO}_3 + 2\text{KHCO}_3 = 14\text{ZnS} + 4\text{Fe}_2\text{O}_3 + \text{K}_2\text{S}_2\text{O}_3 + 16\text{CO}_2 + \text{H}_2\text{O}$, and with **lead carbonate**, the reaction was symbolized: $8\text{FeS}_2 + 14\text{PbCO}_3 + \text{Na}_2\text{CO}_3 = 14\text{PbS} + 4\text{Fe}_2\text{O}_3 + \text{Na}_2\text{S}_2\text{O}_3 + 15\text{CO}_2$. Since pyrite and marcasite produce ferric oxide when treated with zinc carbonate in alkaline soln., in the absence of oxygen, he assumed that the molecule is ferric sulphide in combination with sulphur $\text{Fe}_2\text{S}_3(\text{S})$. The sulphur reacts: $4\text{S} + 3\text{Na}_2\text{CO}_3 = 2\text{Na}_2\text{S} + \text{Na}_2\text{S}_2\text{O}_3 + 3\text{CO}_2$; and $\text{S} + \text{Na}_2\text{S} = \text{Na}_2\text{S}_2$; while the ferric sulphide reacts: $\text{Fe}_2\text{S}_3 + 3\text{Na}_2\text{CO}_3 \rightleftharpoons \text{Fe}_2\text{O}_3 + 3\text{Na}_2\text{S} + 3\text{CO}_2$. If the sulphide in soln. is removed by precipitation, as is the case when the reaction occurs in the presence of heavy metal carbonates, the reaction may proceed to an end. This shows how, in nature, pyrite may pass into hæmatite without oxidation.

J. Krutwig found that when pyrites mixed with **sodium chloride** is heated in a current of air, sodium sulphate, ferric chloride and oxide, and chlorine are evolved; if steam be present, hydrogen chloride and not chlorine is given off. A. P. Brown observed that at ordinary temp., cold or boiling, a 10 per cent. soln. of **copper sulphate** has very little action on pyrite or marcasite, but if the mixtures be heated in sealed tubes for 6 hrs. at 200° , all the iron of marcasite passes into soln. as ferrous sulphate, while with pyrite the product contains 2 mols of ferric sulphate for 1 mol of ferrous sulphate. He concluded therefore that the iron of marcasite is wholly in the ferrous condition, $\text{Fe}''\text{S}_2$, whilst that of pyrite is four-fifths ferric, and one-fifth ferrous, $\text{Fe}''\text{S}_2(\text{Fe}'''\text{S}_2)_4$. H. N. Stokes, however, found that at 200° , the soln. of copper sulphate decomposes marcasite more rapidly than pyrite; ferrous and ferric salts are formed in both cases, the former being found wholly in soln., the latter in the precipitate; there is no marked difference in the relative amounts of ferrous and ferric salts in either case; and the precipitate also contains cuprous sulphide and oxide, and possibly copper as well. The formation of a ferric salt is to be ascribed to the action of ferrous salt on the cupric salt, whilst some oxidation of sulphur to sulphuric acid occurs; and any ferric salt which is not precipitated will be reduced by the sulphides. The relative proportions of ferrous and ferric salts depend on the establishment of an equilibrium between the soln. and the products of the decomposition of the pyrite or marcasite, and not on any fundamental chemical difference in the two minerals. In the reaction with a neutral soln. of copper sulphate and marcasite or pyrite, at 100° to 200° , the sulphur is not completely oxidized since cupric and cuprous sulphides are formed: $5\text{FeS}_2 + 14\text{CuSO}_4 + 12\text{H}_2\text{O} = 7\text{Cu}_2\text{S} + 5\text{FeSO}_4 + 12\text{H}_2\text{SO}_4$ in which 30 per cent. of the sulphur is oxidized; and $4\text{FeS}_2 + 7\text{CuSO}_4 + 4\text{H}_2\text{O} = 7\text{CuS} + 4\text{FeSO}_4 + 4\text{H}_2\text{SO}_4$ in which 12.5 per cent. of the sulphur is oxidized. The reaction is more complex than this because of the interaction of the sulphides with the sulphate soln. E. G. Zies and co-workers found that when pyrite is heated in a sealed tube with a soln. of copper sulphate, covellite and chalcocite are formed. In the presence of quartz, 99.3 per cent. of the copper is converted to cuprous sulphide. The reaction was also studied by A. P. Brown, E. C. Sullivan, F. F. Grout, and G. S. Nishihara. When pyrite is similarly treated with a neutral soln. of **cupric chloride**, H. N. Stokes observed that the mineral is completely converted into ferrous salt and sulphuric acid with a corresponding reduction of the copper from the cupric to the cuprous state in accord with the equation: $\text{FeS}_2 + 14\text{CuCl}_2 + 8\text{H}_2\text{O} = 14\text{CuCl} + \text{FeCl}_2 + 2\text{H}_2\text{SO}_4 + 12\text{HCl}$. A. P. Brown observed that **silver nitrate** readily decomposes pyrite and marcasite forming ferrous and ferric salts; but the results with **silver sulphate** were indefinite. S. A. Kamenezky studied the action of silver nitrate. According to K. Kinoshita, when marcasite is boiled in a 3 per cent. silver nitrate solution, its surface tarnishes to tobacco-brown, then red, and finally blue, while pyrite becomes only slightly brownish. In the reaction, ferrous sulphate, sulphuric acid, and basic ferric sulphate are formed, but in different proportions for the two minerals. J. Lemberg found

that at 70° a sulphuric acid soln. of silver sulphate colours pyrite and marcasite reddish with a violet tinge, and in the cold some silver is formed. A. P. Brown said that a soln. of **gold chloride** is readily decomposed by marcasite and pyrite forming ferrous and ferric salts. According to W. Skey, marcasite and pyrite in soln. of silver or gold salts, at ordinary temp., are slowly covered with a film of silver or gold. Marcasite acts more rapidly than pyrite. These reactions were also examined by M. Leo, F. Zambonini, C. Palmer and E. S. Bastin, and S. Meunier. According to F. Martin and O. Fuchs, when pyrite mixed with **calcium sulphate** is heated to 700°, half the sulphur is evolved as sulphur dioxide, and a part is given off as sulphur. W. O. Hickok observed no reaction with a soln. of **stannous chloride**. According to H. N. Stokes, when marcasite or pyrite is heated with a soln. of **lead chloride**, in a sealed tube filled with carbon monoxide, for 12 hrs. at 180°, galena and lead sulphide are formed: $4\text{FeS}_2 + 7\text{PbCl}_2 + 4\text{H}_2\text{O} = 7\text{PbS} + 4\text{FeCl}_2 + \text{H}_2\text{SO}_4 + 6\text{HCl}$.

A. P. Brown studied the action of an aq. soln. of **potassium permanganate** on pyrite and marcasite, and found that the relative proportions of sulphur oxidized by 0.01N-KMnO₄, and by 1, 3, and 5 per cent. soln. at different temp., were as follow:

Time (hrs.)	0.01N-KMnO ₄		1 per cent. KMnO ₄		3 per cent. KMnO ₄		5 per cent. KMnO ₄	
	1	5	1	5	1	5	1	5
20° { Pyrite	0.78	1.72	1.72	1.80	1.65	2.81	2.39	2.79
{ Marcasite	1.07	2.38	1.22	2.23	2.72	2.83	2.10	3.39
100° { Pyrite	4.05	5.64	6.03	6.88	5.52	11.08	7.95	14.98
{ Marcasite	3.17	5.61	6.43	9.10	5.25	7.55	8.38	16.36

Whilst the total sulphur oxidized by the action of an excess of permanganate in a given time is greater in the case of marcasite than of pyrite, no relation was observed between the amount of sulphur oxidized and the quantity of mineral decomposed. H. N. Stokes found that an acidic soln. of potassium permanganate attacks marcasite more quickly than pyrite, but the difference is not great enough to be used as a means of measuring the relative proportions of the two minerals in a mixture.

L. L. de Koninck observed that **ferric salts**—ferric chloride or ammonium iron-alum—attack pyrite at 170° to 200°, forming a ferrous salt and sulphuric acid; whilst J. H. L. Vogt found that pyrite is slowly attacked by a 30 per cent. soln. of ferric chloride in the cold, forming a trace of sulphuric acid; and A. A. Julien observed that a soln. of ferric chloride is reduced by marcasite. F. A. Eustis said that with pyrite, the reaction: $2\text{FeCl}_3 + \text{FeS}_2 = 3\text{FeCl}_2 + 2\text{S}$ is 40 per cent. off completion. According to R. J. Traill and W. R. McClelland, a soln. of ferric chloride attacks pyrrhotite but not pyrite. The reaction was studied by E. Kopp, W. F. Hillebrand and H. N. Stokes, G. S. Nishihara, and F. F. Grout. H. N. Stokes found that boiling dil. soln. of ferric salts attack pyrite rapidly, the action is slow, but appreciable, with cold soln., and the difference in the effects with pyrite and marcasite are so marked that the reaction can be utilized quantitatively for determining the proportions of the two minerals in a mixture. The method was also examined, and employed by E. T. Allen and co-workers—*vide supra*. The reaction may be regarded as taking place in two stages: $\text{FeS}_2 + \text{Fe}_2(\text{SO}_4)_3 = 3\text{FeSO}_4 + 2\text{S}$; and $2\text{S} + 6\text{Fe}_2(\text{SO}_4)_3 + 8\text{H}_2\text{O} = 12\text{FeSO}_4 + 8\text{H}_2\text{SO}_4$. A soln. containing a gram of ferric iron per litre in the form of ammonium ferric alum is a convenient strength to employ. The percentage of sulphur oxidized varies with the concentration of the ferric salt, so that the percentage decreases as the reduction proceeds. Thus:

Pyrite	{ Fe reduced	.	.	67.8	88.7	95.2	100
	{ S oxidized	.	.	71.4	65.2	63.2	60.4
Marcasite	{ Fe reduced	.	.	69.2	78.5	100.0	
	{ S oxidized	.	.	23.2	22.5	16.2	

and at 20° and 100° the percentages of sulphur oxidized when the reduction was

completed were respectively 80.8 and 60.4 with pyrite, and 30.6 and 17.4 with marcasite. The general results show that when pyrite or marcasite is boiled with an excess of a soln. of ferric salt until the reaction is complete, the ratio of sulphur oxidized to mineral decomposed is definite and characteristic of each mineral when standard conditions are employed. The amount of sulphur oxidized in pyrite is about 60.4 per cent. and in marcasite about 18.0 per cent. of the total sulphur. These figures are called the *characteristic oxidation coefficients*.

§ 43. Ferrous Sulphate

In the first century of our era, Dioscorides, in his *Περὶ ὕλης ἰατρικῆς*, used the term *χαλκανθον*, *chalcanthon*,—from *χαλκός*, copper; *ἄνθος*, flower—which is what was later called **vitriol**. He said (5. 74) :

Chalcanthum is a solidified liquid which appears in three forms. One kind is produced from the liquidus which trickle down drop by drop, and congeal in certain mines, and hence the Cyprian miners call it *stalactis*, and Petesius called it *pinarion*. A second kind collects in certain caverns, and is afterwards poured into trenches, where it congeals, whence it derives its name *pectos*. The third kind is called *hepenthon*, and it is made mostly in Spain. It has a beautiful colour, but is weak. It is prepared by digesting it with water, boiling the liquid, and then transferring it to tanks to settle. After some days, it congeals and separates into many small pieces, having the form of dice, which stick together like grapes. The most valuable kind is blue, heavy, dense, and translucent.

Contemporaneously with Dioscorides, Pliny, in his *Historia naturalis* (36. 32), designated the same substance *atramentum sutorium*. The literal meaning of the term is "shoemaker's blacking," and these words were used because the substance was employed for blackening leather. Pliny said :

The name *chalcānthum* given by the Greeks to *atramentum sutorium* shows that they recognized its relationship to copper. There is no substance of an equally miraculous nature. It is made in Spain from wells of this kind of water. This water is boiled with an equal quantity of pure water, and then poured into wooden tanks (fish-ponds). Across these tanks are fixed beams, to which hang cords stretched by little stones. Upon these cords adheres the *limus* in drops of a vitreous appearance, somewhat resembling a bunch of grapes. After removal, it is dried for about thirty days. It is of a blue colour, and of a brilliant lustre. It is very like glass. Its solution is the blacking used for colouring leather. Chalcanthum is made in many other ways. Its kind of earth is sometimes dug from ditches, from the sides of which exude drops, which solidify by the winter frosts into icicles, called *stalagmia*, and there is none more pure. When its colour is nearly white, with a slight tinge of violet, it is called *leukvion*. It is also made in rock basins, the rain-water collecting the *limus* into them, where it becomes hardened. It is also made, in the same way as salt, by the intense heat of the sun. Hence it is that some distinguish two kinds, the mineral, and artificial. The latter is paler than the former, and is as much inferior to it in quality as it is in colour.

According to K. B. Hofmann,¹ the *chalkanthon* or *chalkanthos* of the ancients was iron-vitriol contaminated with copper sulphate, and J. Berendes said that probably the same substance was called *chalcites*; whilst the fourth-century writer Marcellus Burdigallensis applied the term *chalcanthum viride cyprium* to *atramentum sutorium*. This compound was also described in the second century by C. Galen, in his *De compositione medicamentorum*; and, according to E. Darmstädter, it is alluded to in Geber's *De investigatione perfectionis*.

The term *vitriol* is mentioned in a work on chemical technology—*Compositiones ad tingenda*—dating, probably, from the beginning of the eighth century; and the term is used for an impure ferrous sulphate. The word was employed by Albertus Magnus, who, early in the thirteenth century, in the fifth book of his *De rebus metallicis et mineralibus*, said that *atramentum viride a quibusdam vitreolum vocatur*—"the term *vitriol* is applied to green atrament" (ferrous sulphate)—so that G. Agricola could say, in his *De natura fossilium* (Basileæ, 213, 1546), that in recent years the name *vitriolum* has been applied to this substance. The term *vitriol* comes from the Latin *vitrium*, glass, in allusion to the glassy appearance of the crystals of the vitriols. Although Pliny emphasizes the blue colour of vitriol (copper sulphate), his solution for colouring leather was almost certain to have been ferrous sulphate. Both iron and copper sulphates were thus known to the Romans, but the two substances were not clearly distinguished the one from the other. G. Agricola said that there are three varieties of *atramentum sutorium*—*viride* (green), *cæruleum* (blue), and *candidum* (white). These no doubt respectively indicate ferrous, copper, and zinc sulphates. The pseudonymous Basil Valentine, in the sixteenth or seventeenth century, in his *Von den natürlichen und ubernatürlichen Dingen* (Leipzig, 1624), said that when mars (iron) is dissolved in oil of vitriol *vitriol of Mars* is formed; and in his *Letztes Testament* (Strassburg, 1651), as well as his *Haliographia* (Bononiæ, 1644), he said:

Calcine a mixture of equal parts of the filings of Mars and sulphur in a brick kiln until the colour is purple, then pour on it distilled water or vinegar which extracts a green colour. Abstract two parts of that water, and let it shoot (crystallize). Thus you have noble vitriol. . . . Return thanks to God, the creator of minerals, metals, and all other things.

G. Agricola, in his *De re metallica* (Basileæ, 1556), said that vitriol can be made by four different processes. In two of these methods mine-water containing vitriol is collected either by means of buckets or by pumping and evaporating in pits as described by Dioscorides, and Pliny. In a third method, melanteria, sory, chalcitis, or misy—preferably the two former—was weathered, the soluble matters extracted with water, and the solution evaporated for crystallization. According to H. C. and L. H. Hoover, the term *misy* referred to a yellow, ochreous material, and *sory*, a blackish stone, both impregnated with vitriol; *chalcitis* is referred to partially decomposed pyrites, and *melanteria*—from μέλαν, ink—to a native vitriol—the modern melanerite, hydrated ferrous sulphate. J. D. Dana suggested that misy

was in part copiapite, a basic ferric sulphate. G. Agricola's objections to misy and chalcite may have been due to their copper contents. The fourth method, from vitriolic earth or stones, is thus described :

The ore is at first carried and heaped up, and is then left for five or six months exposed to the rain of spring and autumn, to the heat of summer, and to the rime and frost of winter. It must be turned over several times with shovels, so that the part at the bottom may be brought to the top, and it is thus ventilated and cooled ; by this means the earth crumbles up and loosens, and the stone changes from hard to soft. Then the ore is covered with a roof, or else it is taken away and placed under a roof, and remains in that place six, seven, or eight months. Afterwards as large a portion as is required is thrown into a vat, which is half-filled with water ; this vat is one hundred feet long, twenty-four feet wide, eight feet deep. It has an opening at the bottom, so that when it is opened the dregs of the ore from which the vitriol comes may be drawn off, and it has, at the height of one foot from the bottom, three or four little holes, so that, when closed, the water may be retained, and when opened the solution flows out. Thus the ore is mixed with water, stirred with poles and left in the tank until the earthy portions sink to the bottom and the water absorbs the juices. Then the little holes are opened, the solution flows out of the vat, and is caught in a vat below it ; this vat is of the same length as the other, but twelve feet wide and four feet deep. If the solution is not sufficiently vitriolous it is mixed with fresh ore ; but if it contains enough vitriol, and yet has not exhausted all of the ore rich in vitriol, it is well to dissolve the ore again with fresh water. As soon as the solution becomes clear, it is poured into the rectangular leaden caldron through launders, and is boiled until the water is evaporated. Afterwards as many thin strips of iron as the nature of the solution requires, are thrown in, and then it is boiled again until it is thick enough, when cold, to congeal into vitriol. Then it is poured into tanks or vats, or any other receptacle, in which all of it, apt to congeal, does so within two or three days. The solution which does not congeal is either poured back into the caldron to be boiled again, or it is put aside for dissolving the new ore, for it is far preferable to fresh water. The solidified vitriol is hewn out, and having once more been thrown into the caldron, is re-heated until it liquefies ; when liquid, it is poured into moulds that it may be made into cakes. If the solution first poured out is not satisfactorily thickened, it is condensed two or three times, and each time liquefied in the caldron and re-poured into the moulds, in which manner pure cakes, beautiful to look at, are made from it.

The oxidation of pyrites has been previously described. N. Lemery discussed the contamination of iron-vitriol with copper-vitriol, and J. F. Viganí obtained green iron-vitriol by the action of iron on blue copper-vitriol until all the copper is precipitated from the soln. by the metallic iron. N. Lemery showed that a mixture of sulphur and iron-filings in contact with water becomes heated—*vide supra*, chemical properties of iron—and N. Lefèvre observed that when a mixture of iron-filings and sulphur is weathered, iron-vitriol is formed. Crystals of *vitriolum martis* were prepared by J. R. Glauber, and G. E. Stahl, in the seventeenth and eighteenth centuries, by evaporating a soln. of iron in sulphuric acid.

The transformation of iron pyrites into iron-vitriol by weathering was a puzzle to the early chemists, and the history was discussed by H. Kopp, and E. O. von Lippmann. In 1669, J. Mayow had the right explanation, for he said that the acid spirit of which vitriols are composed seems to be produced by the action of the nitro-aerial spirit on the sulphur of pyrites, the acid spirit then unites with the iron to form vitriol. He added :

Vitriols are produced from the stone or rather the saline-sulphureous earth usually called marchasite (pyrites), and from it on the application of fire the flowers of common sulphur are elicited in considerable abundance. But after this earth has been exposed for some time to the air and wet weather and then (as its nature is) has fermented spontaneously, it will be found to be richly impregnated with vitriol. No doubt the nitro-aerial spirit, effervescing with the metallic sulphur of these marchasites, converts their more fixed part into an acid liquid, which, directly it is produced, attacks the metallic particles of the said stone and draws them out and at last coalesces with them to form vitriol.

J. F. Henckel supposed that the pyrites abstracts salty or acidic particles from the air, and is thus converted into vitriol ; and G. Brandt, that the pyrites, by taking up moisture from the air, passes into vitriol. The advocates of the phlogiston theory—*e.g.*, G. A. Scopoli—believed that the conversion of pyrites to vitriol was a process involving the removal of phlogiston, but A. L. Lavoisier proved that oxygen

is absorbed by the pyrites whereby it is converted into vitriol. In other words, *the oxidation of the sulphide—pyrites—transforms it into a sulphate—vitriol*. This interpretation of the phenomenon of the weathering of pyrites was generally accepted as the antiphlogiston doctrine and became the dominant theory in chemistry.

It was observed that an aq. soln. of vitriol becomes turbid when it is exposed to the air. T. Bergman showed that this is due to the absorption of oxygen from the atmosphere so that the iron in the soln. becomes a stronger calx. In this state, it requires more acid to maintain it in soln. This, by the antiphlogiston theory, means that the ferrous sulphate in soln. is oxidized by exposure to air forming ferric sulphate. J. L. Proust, however, established the existence of two iron sulphates as chemical individuals. He showed that the green sulphate contains 27 per cent. of oxygen, whilst the red variety contains 48 per cent. The green, lower sulphate came to be called **ferrous sulphate**, $\text{FeSO}_4 \cdot n\text{H}_2\text{O}$, and the red, higher sulphate, **ferric sulphate**, $\text{Fe}_2(\text{SO}_4)_3 \cdot n\text{H}_2\text{O}$. J. L. Proust showed that the chemical properties of the two sulphates are quite different, and that oxidizing agents—*e.g.*, nitric acid—convert ferrous into ferric sulphate, whilst reducing agents—like hydrogen sulphide—convert ferric into ferrous sulphate.

Two hydrated ferrous sulphates occur in nature—the monohydrate, and the heptahydrate. The heptahydrate occurs in two crystalline forms. Analyses of natural waters carrying ferrous sulphate in solution were reported by T. Pusch,² H. Bley, L. von Barth and R. Wegscheider, J. C. Essener, G. C. Wittstein, and N. O. Hamberg. Ferrous sulphate often accompanies pyrite as an efflorescence—*e.g.*, at Copperas Mountain, Ohio, where it is associated with alum and pyrite. It also occurs in solution in many mine-waters where it has been formed by the oxidation of pyrite or marcasite. When the water has had the opportunity of concentrating, monoclinic crystals of heptahydrated ferrous sulphate are formed. This has taken place in the mine at Goslar, Harz; at Bodenmais, Bavaria; Falun, Sweden; Hurlet, Scotland; and many other places. The mineral so formed was called *atramentum viride* by C. Gesner; *vitriolum viride*, or *vitriolum ferri*, or *vitriolum martis*, by J. G. Wallerius; *mélantérie*, by F. S. Beudant, and this was altered to **melanterite**, its present name; *luckite*, by A. Carnot; and *alcaparrosa verde*, by A. Raimondi. This is probably the salt described by the ancient writers indicated above, and it is and has been also called *copperas*, and *green vitriol*. A rare rhombic form of the heptahydrate was reported by G. H. O. Volger to occur at Windgälle in the Swiss Canton Uri—*i.e.* the *Pagus tauriscorum* of the Romans; and the mineral was accordingly called **tauriscite**. It was also observed by J. A. Krenner to occur at Schmöllnitz, Slovakia. J. B. Macintosh described an impure monohydrate from Chile, and R. Scharizer applied the term **ferropallidite**, to a sample from Alcapa Rossa, Calama, Chile; and J. A. Krenner called a sample from Schmöllnitz, Slovakia, *schomolnokite*.

Analyses of melanterite were reported by W. T. Schaller,³ G. Vavrinecz, J. Janowsky, J. Thiel, J. E. Edgren, E. Manasse, A. Frenzel, V. Zsivny, A. Carnot, and L. Michel, and the results correspond with monoclinic, heptahydrated ferrous sulphate, $\text{FeSO}_4 \cdot 7\text{H}_2\text{O}$. The analysis of tauriscite reported by G. H. Volger, and J. A. Krenner, agree with the assumption that the rhombic crystals are also heptahydrated ferrous sulphate. The analysis of ferropallidite or schomolnokite, reported by R. Scharizer, and J. Donau, agree that the mineral is monohydrated ferrous sulphate, $\text{FeSO}_4 \cdot \text{H}_2\text{O}$. Analyses of ferrous sulphate were made by T. Thomson.

The preparation of ferrous sulphate.—G. Tammann⁴ noted that anhydrous ferrous sulphate is formed when a mixture of lead sulphate and iron is heated to about 540° ; the reaction is turbulent, and is symbolized: $\text{PbSO}_4 + \text{Fe} = \text{Pb} + \text{FeSO}_4 + <11 \text{ Cals.}$ L. Hackspill and co-workers noted that it is formed in a similar way by heating iron with an excess of alkali sulphate. B. Neumann observed that ferrous sulphate is formed when a mixture of sulphur dioxide and oxygen acts on ferrous oxide: $\text{Fe}_3\text{O}_4 + 2\text{SO}_2 + \text{O}_2 \rightleftharpoons \text{FeSO}_4 + \text{Fe}_2\text{O}_3 + \text{SO}_3$; and ferrous sulphate

may be regarded as an intermediate stage in the catalytic action of iron oxide in the oxidation of sulphur dioxide to the trioxide. According to G. Keppeler, some ferric oxide is formed. The Farbwerke vorm. Meister Lucius und Brüning, and J. d'Ans suggested that ferrous sulphite is formed as a transient intermediate product, and that this is oxidized to the sulphate. G. Keppeler and J. d'Ans noted that ferrous sulphate is formed when sulphur dioxide acts on ferric sulphate: $\text{Fe}_2(\text{SO}_4)_3 + \text{SO}_2 \rightleftharpoons 2\text{FeSO}_4 + 2\text{SO}_3$. R. Cox discussed the formation of ferrous sulphate when hydrogen sulphide acts on ferric oxide or hydroxide in the purification of coal-gas. E. T. Allen and co-workers noticed that ferrous sulphate is formed when pyrrhotite, marcasite, or pyrite is triturated in a mortar, or heated in air to 100° ; E. Kothny, when pyrite is heated in air to 250° to 290° ; and H. Saito, P. Truchot, and A. W. Warwick also noted that ferrous sulphate is formed as an intermediate or by-product in the oxidation of pyrites—F. Warlimont observed that with pyrrhotite, the formation of ferrous sulphate begins about 400° , and at 420° , to 430° , 11.0, 15.6, and 20.2 per cent. were formed respectively in 3, 4, and 5 hrs. J. Kolb noted the formation of ferrous sulphate when pyrite is heated with copper oxide in air; and V. Tafel and E. Greulich, when chalcopyrite is heated above 300° .

R. Brandes, and F. Stolba showed that hydrated ferrous sulphate can be dehydrated at a suitable temp. A. Adolphs, and F. Krafft found that the salt is dehydrated in the high vacuum of the cathode light at 280° ; H. Saito, K. Friedrich, and K. Friedrich and A. Blicke observed a break in the time-temp. curve when hydrated ferrous sulphate is heated in air, and this corresponds with the passage of the monohydrate to the anhydrous salt. T. E. Thorpe and J. I. Watts heated the hydrate in hydrogen to prevent oxidation—H. Precht and K. Kraut recommended 100° ; E. Kothny, 250° ; J. Kendall and A. W. Davidson, 270° ; J. Kendall and A. W. Davidson, and F. Warlimont, 290° ; J. d'Ans, and G. Keppeler and J. d'Ans, 300° to 320° ; and J. A. Hedvall and J. Heuberger, 300° in carbon dioxide. R. de Forcrand observed that in hydrogen, the last mol. of water is slowly expelled at 180° , but recommended 250° for the completion of the action; he added that about 1.5 per cent. of a basic sulphate is unavoidably formed at the same time. E. Greulich said that all the water is not expelled from ferrous sulphate in hydrogen even at 200° , and that 1.9 per cent. of ferric sulphate is formed; he recommended treating ferrous chloride with 100 per cent. sulphuric acid in an atm. of hydrogen, and driving off the excess of sulphuric acid at 230° in an atm. of hydrogen. T. Bolas, and A. Bussy and L. R. Lecanu obtained what they regarded as the anhydrous salt by treating the hydrated salt at ordinary temp. with sulphuric acid of sp. gr. 1.843. E. Howl and F. Perry also recovered the salt in the anhydrous form from acidic liquors by evaporating the lye to a concentration of 75 per cent. free sulphuric acid. A. C. Knowles evaporated the soln. of ferrous sulphate by spraying it in hot air or hot gas.

The hydrated forms of ferrous sulphate.—J. R. Glauber, and G. E. Stahl prepared a soln. of ferrous sulphate by dissolving iron in sulphuric acid until the acid is saturated, and evaporating the filtered soln. for crystallization. Ferrous sulphate absorbs oxygen from the air so readily that the crystals obtained by evaporating the aq. soln. are liable to be contaminated with ferric sulphate. P. A. von Bonsdorff recommended saturating dil. sulphuric acid (1:4 or 1:5) with iron by boiling the mixture in a narrow-necked flask until it is near the point of crystallization. The liquid is then strained through a filter, moistened with water, into a vessel rinsed out with dil. sulphuric acid. The acid prevents the liquid from hydrolysis, and the funnel should have a long neck reaching to the bottom of the vessel. The crystals are allowed to drain, and dried by pressure between bibulous paper at 30° . P. Geiseler, and A. Piccini and F. M. Zuco employed a similar process. E. Cohen and A. W. Visser tried to prevent the oxidation of the soln. by using an atm. free from air in a Soxhlet's apparatus and air-free water. C. L. Mayer electrolyzed soln. of alkali sulphate or hydrosulphate with electrodes

of iron, or of oxide or carbonate minerals, and obtained soln. from which hydrated ferrous sulphate could be obtained by crystallization.

W. Kistiakowsky noticed that when a strip of iron is dipped in a 2 per cent. soln. of sodium sulphate and exposed to air containing carbon dioxide, the iron is eroded near the interface of air and soln. to form sodium carbonate and ferrous sulphate. A soln. of ferrous sulphate is formed when ferrous oxide or hydroxide is dissolved in sulphuric acid. J. Behrens observed that a slurry of gypsum and freshly-precipitated ferrous hydroxide reacts in an atm. of carbon dioxide to form ferrous sulphate: $\text{FeO} + \text{CO}_2 + \text{CaSO}_4 = \text{CaCO}_3 + \text{FeSO}_4$. I. Sorganuma noticed that the sulphurous gases from mineral springs act on ferruginous rocks and clays producing melanterite. G. C. Westby, and D. Peniakoff described processes for using sulphurous, waste gases from the industries for making ferrous sulphate soln. C. Winkler, and G. Agde also utilized waste acid, or acid from the lead chambers for preparing ferrous sulphate from iron; and instead of using iron, A. Buisine used incompletely roasted pyrites; the waste oxide from aniline works; A. Pezzolato, pyrite reduced by preheating with carbon; G. Meunier, artificial ferrous sulphide; G. Kogan, and C. Mène, blast-furnace slags; and T. Ritterhaus, spathic iron ore.

J. J. Berzelius obtained a soln. free from ferric salt by dissolving ferrous sulphide in sulphuric acid. A. L. Day obtained mixed copper and ferrous sulphates by the action of dil. sulphuric acid on bornite, or on mixtures of pyrrhotite and chalcocite or covellite. The formation of ferrous sulphate as a stage in the weathering of iron pyrites is a very old process—*vide supra*. It was discussed by A. P. Brown, E. Dittler, T. J. Drakeley, S. H. Emmens, W. Haidinger, A. Lacroix, J. Lefort, W. Thörner, and A. Wurm. E. T. Allen and co-workers obtained a soln. of ferrous sulphate by the action of marcasite or pyrite on a soln. of ferric sulphate; and A. Hutin represented the reaction: $\text{Fe}_2(\text{SO}_4)_3 + \text{FeS}_2 + 2\text{O}_2 = 3\text{FeSO}_4 + 2\text{SO}_2$; and $\text{Fe}_2(\text{SO}_4)_3 + \text{FeS}_2 + 4\text{H}_2\text{O} = 3\text{FeSO}_4 + 2\text{SO}_2 + 4\text{H}_2$. A. and P. Buisine also reduced a soln. of ferric sulphate with iron: $\text{Fe}_2(\text{SO}_4)_3 + \text{Fe} = 3\text{FeSO}_4$. T. von Grothaus found that an alcoholic soln. of ferric sulphate is reduced to ferrous sulphate in a closed vessel by exposure to light; W. H. Ross obtained a similar result by exposing a soln. of sugar and ferric sulphate to ultra-violet light; and A. Kailan, by exposing the soln. to radium rays. W. Feld also discussed the formation of ferrous sulphate by heating soln. of the polythionic acids.

O. Mustad recommended preparing a soln. of ferrous sulphate by dissolving the hydrated salt in water acidified with sulphuric acid, and allowing the soln. to stand for some weeks in contact with iron so as to neutralize the acid, and keep the salt in the ferrous state. A. F. W. von Escher triturated the hydrated salt with reduced iron, dissolved it in water at 60° through which a current of hydrogen was passed, removed the free acid with baryta-water, and allowed the mixture to stand a few days. N. A. Tananaeff dissolved the hydrated salt in boiled water saturated with carbon dioxide, added hydrogenized palladium, and kept the soln. in an atm. of hydrogen; F. W. Horst treated the hot soln. with hydrogen sulphide gas, and then with carbon dioxide. G. Bailhache observed that the aq. soln. can be preserved for a long time in an atm. of carbon dioxide. F. W. Horst said that the soln. can be kept from oxidation, for a short time, by covering it with a layer of benzene.

The pickling of iron with acids, and in some wet processes of extracting products from ferruginous ores, furnishes as waste-products acidic liquors containing ferrous sulphate in soln., and from which the salt can be recovered. This subject was discussed by Bergbau Aktien Gesellschaft Friedrichsseen, S. E. Coburn, G. Agde, E. V. Chambers and co-workers, C. A. Hall, L. Hirt, A. C. Knowles, L. Kugel, L. Simmonds, H. Stähler, H. C. Stewart, L. Thorel, and G. Weintraub.

According to P. A. von Bonsdorff, commercial ferrous sulphate, or green vitriol, or copperas may be contaminated with ferric, cupric, zinc, manganese, tin,

aluminium, magnesium and calcium sulphates, and arsenious acid. The copper and ferric salts can be removed by digesting a soln. of the salt in sulphuric acid with metallic iron, or ferrous sulphide, out of contact with air; the arsenic, copper, and tin can be removed by allowing the soln. saturated with hydrogen sulphide to stand for some days before filtering. H. Wurtz recommended removing copper and ferric salts by digesting the soln. with barium carbonate; and L. Thorel removed zinc and manganese by boiling the soln. with potassium hydrotartrate. The subject was also discussed by C. H. Butcher, E. Merck, and F. Mach and P. Lederle.

The crystals which separate from the aq. soln. at ordinary temp. are the **heptahydrate**, $\text{FeSO}_4 \cdot 7\text{H}_2\text{O}$, and, according to F. Fränckel, the same salt separates from

FIG. 640.—Percentage Solubility of Ferrous Sulphate in Water.

an aq. soln. between -1.821° and 56.7° with soln. containing 14.91 to 35.06 per cent. of FeSO_4 —*vide infra*, Fig. 640. This hydrate is also called *green vitriol*, *copperas*, and *vitriolum martis*. F. Wirth, and F. B. Kenrick studied the conditions under which the heptahydrate separates from soln. containing sulphuric acid—*vide infra*, Fig. 640. R. Brandes observed that the heptahydrate is formed when the crystals of one of the lower hydrates, or of the anhydrous salt are exposed to moist air.

H. Seymour discussed the continuous crystallization of the salt in the course of its manufacture. The crystals of the heptahydrate were analyzed by J. J. Berzelius, T. Bergman, R. Kirwan, F. Thomas, E. Mitscherlich, and T. Graham; the analyses of melanterite have been previously indicated. J. B. Berthemot recommended purifying the crystals by allowing the salt to crystallize from water acidulated with sulphuric acid; then boiling 500 parts of the crystals with 550 parts of water, and 8 parts of iron turnings; filtering the boiling soln. into a mixture of 375 parts of alcohol of sp. gr. 0.84, and 8 parts of sulphuric acid with constant stirring; straining the cold liquid from the small crystals which form; draining the crystals on linen; and drying them between bibulous paper, constantly renewed. The alcohol retains in soln. any ferric salt which may be present, and the solubility of that salt is increased by the sulphuric acid. N. A. Tananaeff recommended washing out the alcohol by boiled water saturated with carbon dioxide. Processes were also described by F. Fränckel, E. Jordis and H. Vierling, L. Thorel, G. Ruspini, and H. Vierling.

A. F. de Fourcroy found that cold water dissolves nearly half its weight of the heptahydrate, and boiling water very nearly its own weight. Observations were also made by A. Ure, T. Bergman, E. Tobler, H. G. Greenish and F. A. U. Smith, and R. Brandes and E. Firnhaber. H. Schiff found that a soln. sat. at 15° contains 37.2 per cent. of $\text{FeSO}_4 \cdot 7\text{H}_2\text{O}$; C. von Hauer, 17.02 per cent. FeSO_4 at 11° to 14° ; W. Stortenbeker, 26.69 per cent. FeSO_4 at 25° ; F. Wirth gave 22.84 per cent. FeSO_4 at 25° ; G. Agde and H. Barkholt, 13.80 at 1° ; 17.10 at 9.6° ; 21.30 at 21° ; 22.98 at 25° ; 26.56 at 34° ; 30.04 at 43° ; 34.50 at 54° ; and 30.20 at 80° ; and V. J. Occleshaw, 22.98 at 25° . F. A. H. Schreinemakers found 24.9 per cent. FeSO_4 at 30° . R. Brandes observed that the increase in the solubility of the salt with a rise of temp. continues up to 87.5° , and thereafter the solubility decreases with a rise of temp. He attributed this to hydrolysis whereby a white product is formed. A transition point at about 63.5° was observed by G. J. Mulder; at 64° by W. A. Tilden; and at 65° by A. Étard. I. Koppel thought there

was one at 40° . A. Étard gave for the percentage solubility, S , per cent. FeSO_4 :

	-1°	24°	52°	60°	67°	94°	102°	112°	130°	152°
S	13.0	22.7	32.5	36.4	37.7	36.7	34.7	28.0	17.3	2.5

so that from -2° to 65° , $S=13.5+0.3788\theta$; from 65° to 98° , $S=37.5$, i.e. a constant; from 98° to 156° , $S=37.5-0.6685\theta$; and at 156° , the salt is practically insoluble. F. Fränckel obtained for the percentage solubility:

	-0.685°	-1.824°	0°	20.10°	50.21°	56.7°	60.01°	64.00°	68.02°	90.13°
S	5.1811	14.91	13.53	21.00	32.71	35.06	35.46	35.65	35.96	27.15
Solid phase	Ice		$\text{FeSO}_4 \cdot 7\text{H}_2\text{O}$			$\text{FeSO}_4 \cdot 4\text{H}_2\text{O}$		$\text{FeSO}_4 \cdot \text{H}_2\text{O}$		

There is a region of metastability for the tetrahydrate when at 65.00° and 70.04° , the respective values of S are 35.73 and 35.93 per cent. FeSO_4 . F. K. Cameron considers that the solid phase above 67.4° is not, as indicated by F. Fränckel, the monohydrate, but rather the dihydrate. According to F. Fränckel, the **eutectic temperature**, at -1.824° and 14.91 per cent. of FeSO_4 , was given by F. Guthrie at -2° , with 16.95 per cent. of FeSO_4 . I. Koppel gave -2° ; H. Gröber, -1.8° ; and E. W. Washburn and E. R. Smith, -1.80° . According to F. Fränckel, the **transition temperature** for the hepta- and tetrahydrates: $\text{FeSO}_4 \cdot 7\text{H}_2\text{O} \rightleftharpoons \text{FeSO}_4 \cdot 4\text{H}_2\text{O} + 3\text{H}_2\text{O}$ occurs at about 56.7° ; and for the tetra- and monohydrates: $\text{FeSO}_4 \cdot 4\text{H}_2\text{O} \rightleftharpoons \text{FeSO}_4 \cdot \text{H}_2\text{O} + 3\text{H}_2\text{O}$, at about 64° . There is here no evidence of the formation of the alleged hexa-, penta-, tri-, and dihydrates. In agreement with these observations by F. Fränckel, W. Müller-Erbach found evidence of the mono-, tetra-, and heptahydrates on his vap. press. curves. This also agrees with observations on the system: $\text{FeSO}_4\text{--H}_2\text{SO}_4\text{--H}_2\text{O}$ indicated below. On the other hand, F. K. Cameron observed as an average on a rising and falling temp., breaks corresponding with transitions at 56.8° , 61.0° , 64.4° , 65.8° , and 67.8° . These breaks, along with the solubility data of F. Fränckel, F. Wirth, A. Étard, F. A. H. Schreinemakers, and G. Agde and H. Barkholt, are interpreted by the solubility curve, Fig. 640. The hydrates were studied by E. N. Gapon.

L. de Boisbaudran reported the **hexahydrate**, $\text{FeSO}_4 \cdot 6\text{H}_2\text{O}$, to be formed when a soln. of ferrous sulphate, slightly under-saturated with respect to the heptahydrate, is seeded with a crystal $\text{CoSO}_4 \cdot 6\text{H}_2\text{O}$ obtained from the aq. soln. at 50° . C. Hensgen obtained the hexahydrate by treating the heptahydrate with conc. hydrochloric acid; T. Bolas, by exposing the pyrosulphate to moist air; E. Wiedemann, by melting the heptahydrate at 65° and removing the molten portion; and F. Jeremin obtained colourless plates from a sulphuric acid soln. of ferrous sulphate. E. Cohen and A. W. Visser, L. Rolla, W. C. Schumb, and H. Schottky assumed that the hexahydrate has a real existence, but R. de Forcrand had doubts. In any case, the green, acicular crystals of the hexahydrate are metastable, and soon pass into the heptahydrate.

According to J. C. G. de Marignac, when a soln. of ferrous sulphate in sulphuric acid is evaporated in vacuo, the heptahydrate first separates, then the **pentahydrate**, $\text{FeSO}_4 \cdot 5\text{H}_2\text{O}$, and finally the tetrahydrate. F. K. Cameron doubted if this is an accurate description of the facts. L. de Boisbaudran found that when a soln. of ferrous sulphate is seeded with pentahydrated copper sulphate, pentahydrated ferrous sulphate separates as a metastable phase which is rapidly transformed into the heptahydrate; he added that the pentahydrate is difficult to prepare and it can be obtained only from soln. much supersaturated with respect to the heptahydrate. J. T. Conroy supposed this salt to be present in conc. sulphuric acid soln. of the heptahydrate; and T. Bolas, and J. B. Hannay considered it to be formed by the dehydrating action of sulphuric acid. A. Schrauf reported the pentahydrate to occur in nature in needle-like crystals along with melanterite, and he called the mineral **siderotile**. R. de Forcrand, F. K. Cameron, F. K. Cameron and H. D. Crockford, and G. Agde and H. Barkholt expressed doubts as to the existence of the pentahydrate.

As just indicated, J. C. G. de Marignac considered that when an acidic soln. of ferrous sulphate crystallizes in vacuo, the last crop of crystals is the **tetrahydrate**, $\text{FeSO}_4 \cdot 4\text{H}_2\text{O}$. P. A. von Bonsdorff obtained the tetrahydrate in a similar manner; and H. V. Regnault, by evaporating a soln. of ferrous sulphate at 80° . F. Fränckel showed the conditions of stability of the tetrahydrate, Fig. 640, in aq. soln.; and F. B. Kenrick, the conditions of equilibrium in sulphuric acid soln.—*vide supra*, Fig. 640. F. Fränckel showed that in aq. soln., the salt is stable between 56.7° and 64.0° , and metastable between 64.0° and 70.04° . J. B. Hannay obtained the tetrahydrate by the progressive dehydration of the heptahydrate; and P. A. von Bonsdorff, E. Moles and M. Crespi, J. T. Conroy, W. Müller-Erbach, R. Scharizer, H. O. Hofman and W. Wanjukoff, C. Gaudefroy, R. de Forcrand, and T. E. Thorpe and J. I. Watts obtained this hydrate in a somewhat similar manner.

According to O. B. Kühn, the **trihydrate**, $\text{FeSO}_4 \cdot 3\text{H}_2\text{O}$, is formed as a white crust when a soln. of ferrous sulphate is mixed with a large excess of sulphuric acid; and, according to R. J. Kane, when a soln. of ferrous sulphate, saturated with hydrogen chloride, is allowed to cool. The green crystals of the heptahydrate are mixed with the pale green crystals of the trihydrate. T. Bolas reported the same hydrate to be formed by the action of sulphuric acid on the heptahydrate; and J. B. Hannay, and J. T. Conroy, by the evaporation of a soln. of ferrous sulphate in an excess of sulphuric acid at 60° to 80° . R. de Forcrand could not confirm the existence of the trihydrate. W. Stortenbeker said that ferrous sulphate forms solid soln. with tritaoctohydrated cadmium sulphate, so that the **tritaoctohydrate**, $3\text{FeSO}_4 \cdot 8\text{H}_2\text{O}$, exists only in the isomorphous admixture.

P. A. von Bonsdorff said that when sulphuric acid is slowly added to a sat. soln. of ferrous sulphate, so as not to produce any marked rise of temp., until the sp. gr. is 1.33, and the soln. is evaporated over conc. sulphuric acid, crystals of the heptahydrate appear; and when about two-thirds of the liquid has evaporated, crystals of the tetrahydrate are deposited; then follows a crop of crystals of a basic sulphate; and finally, a dark green, crystalline mass of the **dihydrate**, $\text{FeSO}_4 \cdot 2\text{H}_2\text{O}$, is formed. V. Schemlyanitzuin and N. Dobrovolsky obtained the dihydrate in a vat of copperas. T. Bolas, and J. B. Hannay obtained the dihydrate by the dehydration of the heptahydrate by sulphuric acid; T. E. Thorpe and J. I. Watts, by repeated treatment of the heptahydrate with boiling absolute alcohol; J. T. Conroy, by the action of sulphuric acid on the tetrahydrate; A. Étard, by heating the aq. soln. at temp. up to 160° ; and J. B. Hannay, by heating the heptahydrate, when the dihydrate shows itself as a break in the dehydration curve at 100° . According to F. K. Cameron, the dihydrate appears as a stable phase in contact with its sat. soln. above 67.4° under conditions where F. Fränckel, and others said that the solid phase is the monohydrate. F. K. Cameron also added that the dihydrate is stable at 65° in contact with aq. soln. containing over 2.5 per cent. of sulphuric acid; and he obtained it as a finely-divided, white, crystalline powder which is quite stable in dry air, and which dissolves in water more slowly than the other hydrates.

E. Mitscherlich observed that when the heptahydrate is heated to 140° , in vacuo, the **monohydrate**, $\text{FeSO}_4 \cdot \text{H}_2\text{O}$, is formed, and it persistently retains the odd mol. of water up to between 200° and 300° . K. Klüss obtained the monohydrate by heating the heptahydrate at 200° . G. Keppeler and J. d'Ans poured a feebly acidic soln. of ferrous sulphate into alcohol, and heated the product dried by suction, in a current of hydrogen at 70° , and finally at 150° to 200° . The conditions of stability in aq. soln. are, according to F. Fränckel, indicated in Fig. 640, so that it is considered to be the stable phase in soln. containing 35.57 to 27.15 per cent. FeSO_4 at temp. between 64.0° and 90.13° . F. K. Cameron said that the monohydrate is here mistaken for the dihydrate—*cf.* Fig. 640. W. Müller-Erbach demonstrated the existence of this hydrate from its effect on the vap. press. curve. F. B. Kenrick observed the monohydrate to be the stable phase in the system: $\text{FeSO}_4\text{--H}_2\text{SO}_4\text{--H}_2\text{O}$ in soln. with a mol of SO_3 in 2.186 to 7.93 mols of water.

F. Wirth showed that the transition temp. : $\text{FeSO}_4 \cdot 7\text{H}_2\text{SO}_4 \rightleftharpoons \text{FeSO}_4 \cdot \text{H}_2\text{O} + 6\text{H}_2\text{O}$, is lowered about 25° by sulphuric acid, and he obtained the monohydrate by bringing the heptahydrate in contact with a soln. of concentration exceeding $12.5N\text{-H}_2\text{SO}_4$. D. Link, R. Scharizer, F. Jeremin, A. Étard, H. Lescœur, and A. Scott obtained it by adding conc. sulphuric acid to a sat. soln. of ferrous sulphate. R. Scharizer obtained the monohydrate by allowing the heptahydrate to effloresce for a long period in dry air; and J. B. Hannay, and E. Moles and M. Crespi, by passing air dried by sulphuric acid over the heptahydrate at 100° . R. Scharizer reported the monohydrate to occur with rômerite near Copiapo, Chile, and he called it **ferropallidite**. It was previously observed by J. B. Macintosh. The mineral was also called *szomolnokite*—after Szomolnok, Hungary—and *schmöllnitzite*. D. Florentin said that the monohydrate can be prepared in the following manner; and added that the product is non-hygroscopic, and undergoes no change when kept for long periods, so that it is suitable for use in standardizing such soln. as potassium permanganate, etc.

Dissolve in 200 c.c. of 50 per cent. sulphuric acid, assisted by warming on a water-bath, 400 grms. of ferrous sulphate, purified by re-crystallization several times. Almost as soon as solution is complete, the monohydrate begins to separate as a colourless crystalline powder, which is collected on a suction filter, washed with alcohol or dry acetone, then with dry ether, and finally dried by reduced press. over sulphuric acid. The yield is about 40 grms.

T. Graham, E. Mitscherlich, H. Precht and K. Kraut, J. B. Hannay, T. E. Thorpe and J. I. Watts, G. Keppeler and J. d'Ans, W. Peters, A. Rosentiehl, etc., observed that the heptahydrate gives off six-sevenths of its water at a comparatively low temp., say 115° , but the remainder is not given off until a much higher temp. is attained, say 280° . T. Graham thought that this odd molecule can be expelled without the loss of acid, but R. de Forcrand observed that if the dehydration temp. exceeds 140° , in vacuo, the anhydrous salt is always contaminated with some basic salt. R. Scharizer observed that 3 of the mols. of water are evolved fairly quickly over sulphuric acid in a desiccator, but the other 3 mols. occupy a long time—many months indeed. The first 3 mols. pass off at 40° , and the next 3 mols. at about 70° , but the remaining mol. is retained very tenaciously. T. Graham designated the odd mol. of water, *constitutional water*; J. von Liebig, *Halbhydratwasser*. T. Graham wrote $\text{HO} \cdot \text{Fe} \cdot \text{HSO}_4 + 6\text{H}_2\text{O}$ as the formula for the heptahydrate, and this agrees with the opinions of W. Müller-Erbach, R. Scharizer, and D. Florentin. W. T. Schaller wrote the formula :

and A. Werner, $[\text{Fe}(\text{H}_2\text{O})_6\text{SO}_4] \cdot \text{H}_2\text{O}$. R. Reinicke discussed the spatial arrangement on the assumption that the 6 mols. of water are arranged about the six corners of an octahedron model. In connection with T. Graham's view that the monohydrate is constituted as if it were **ferrous hydroxyhydrosulphate**, $\text{Fe}(\text{OH})(\text{HSO}_4)$, it is interesting to observe that F. B. Kenrick prepared the acidic salt, **ferrous hydrosulphate**, $\text{Fe}(\text{HSO}_4)_2$, i.e. P. A. von Bonsdorff's $\text{FeSO}_4 \cdot \text{H}_2\text{SO}_4 \cdot 6\text{H}_2\text{O}$. This is in accord with C. S. Mummery's theory of the catalytic action of ferrous sulphate on hydrogen dioxide, etc.

The physical properties of ferrous sulphate.—Melanterite occurs massive and pulverulent; but usually in capillary, fibrous, stalactitic, or concretionary forms; its colour is green of various shades, and in the case of thin fibres, or of pulverulent forms, it is almost white. When it has been exposed to the air, it becomes yellowish. A. Bussy and L. R. Lecanu, and C. Hensgen said that the anhydrous sulphate is white, and E. Greulich added that when 1.9 per cent. of ferric sulphate is present, the colour is greyish-white. E. Jordis and H. Vierling, J. S. Anderson, and N. A. Tananaeff said the crystals of the heptahydrate are blue or bluish-green;

and A. Piccini and F. M. Zuco, green. A. P. von Bonsdorff observed that the crystals are blue with a green tinge if free from ferric salt, but if a ferric salt is present the green colour predominates. M. Bamberger and R. Grengg added that the pale green crystals of the heptahydrate become greenish-white when cooled to -190° . C. Heinsgen said that the crystals of the hexahydrate are bright green; L. de Boisbaudran, and J. C. G. de Marignac, that the crystals of the pentahydrate are bluish-green or greenish-blue; P. A. von Bonsdorff, that the crystals of the tetrahydrate are chrysoprase green, pale green, or pale apple-green, without a blue tinge; R. J. Kane, that the crystals of the trihydrate are a much paler green than those of the heptahydrate; P. A. von Bonsdorff, that the crystals of the dihydrate are dark green; and W. Peters described the crystals of the monohydrate as pale yellowish-brown. A. Étard said dirty white, F. Jeremin, and D. Florentin, white. The general result is to show that the heptahydrate is pale greenish-blue, and that the colour weakens as the proportion of water diminishes until the monohydrate appears when it and the anhydrous salt are colourless or white. J. S. Anderson, and T. Dreisch said that dil. aq. soln. with a mol of salt per litre are nearly colourless; but more conc. soln. are pale green. N. A. Tananaeff observed that the pale blue crystals form a colourless soln. which becomes green by oxidation, and later brownish-yellow. R. Peters added that the soln. in contact with a platinum electrode charged with hydrogen, is colourless in thin layers, and pale green in layers of 1 mm. thickness.

T. Bolas said that the anhydrous sulphate furnishes white, microscopic, prismatic **crystals**. According to P. Groth, the crystals of the heptahydrate are monoclinic prisms probably with a pseudorhombohedral structure. V. R. von Zepharovich gave for the axial ratios $a : b : c = 1.1828 : 1 : 1.5427$, and $\beta = 104^{\circ} 15.5'$; and W. T. Schaller, $1.1828 : 1 : 1.5421$; and $\beta = 104^{\circ} 14'$. The crystals were examined by H. E. Armstrong and E. H. Rood, H. Baumhauer, T. Bergman, M. H. Hey, F. S. Beudant, I. Eques a Born, H. J. Brooke, L. J. M. Daubertin, C. von Hauer, R. J. Haiiy, R. Kirwan, F. Mohs, C. Pape, J. C. Poggendorff, C. F. Rammelsberg, G. Rose, J. B. L. Romé de l'Isle, J. G. Wallerius, W. H. Wollaston, and C. Wöllner. The **habit** of the crystals is in short columns or thick plates with well-developed basal surfaces; when grown in soln. containing copper sulphate, H. Baumhauer found that the crystals are pseudorhombohedral; and in soln. with alum, C. Wöllner said that the crystals are regular octahedra. F. S. Beudant observed the effect of sodium borate and phosphate, lead sulphate, and hydrochloric and sulphuric acids; H. Reinsch observed that the presence of nitric acid had no influence on the habit of the crystals. O. Mügge discussed the formation of capillary, curved crystals. R. O. Lehmann described the effect of rapid cooling of hot, sat. soln. in the crystallization; and D. Gernez, the crystallization of supersaturated soln. J. M. Thomson studied the seeding of supersaturated soln. of magnesium sulphate with heptahydrated ferrous sulphate. E. Küster observed the **rhythmic crystallization** of the salt in gelatine. A. Drevermann measured the **rate of crystallization**; and C. L. Wagner, the rate of dissolution of the crystals. G. Schendell said that the rate of crystallization is accelerated in an electric field; and R. Hunt, S. Meyer, and G. Roasio studied the effect of a magnetic field on the crystallization of the salt. The **cleavage** of the crystals of the heptahydrate is perfect on the (001)-faces, and indistinct on the (110)-face. R. Scharizer said that the (010)-cleavage of the tetrahydrate is perfect. The **optical character** of the crystals of the heptahydrate is positive; and A. des Cloizeaux found the **optic axial angles** $2H_0 = 86^{\circ} 51'$, $2H_0 = 94^{\circ} 13'$, and $2V_a = 86^{\circ} 21.5'$ for red-light; $2H_a = 86^{\circ} 49'$, $2H_0 = 94^{\circ} 21'$, and $2V_a = 86^{\circ} 13'$ for yellow-light; and $2H_a = 86^{\circ} 31'$, $2H_0 = 94^{\circ} 46'$, and $2V_a = 85^{\circ} 53.5'$ for blue-light. M. Eroféef gave $2V = 85^{\circ} 31'$ for Li-light; $85^{\circ} 27'$ for Na-light, and $85^{\circ} 23'$ for blue-light. R. Scharizer found $2V$ to be large for the tetrahydrate. The **corrosion figures** were studied by H. Baumhauer, and E. Blasius, and the etching of the crystals by efflorescence, by E. Blasius, C. Gaudefroy, and C. Pape. H. G. K. Westenbrink found that the

X-radiograms correspond with a space-lattice having $a=15.34$ Å., $b=12.98$ Å., and $c=20.02$ Å. for the elementary cell, and 16 mols. $\text{FeSO}_4 \cdot 7\text{H}_2\text{O}$ per cell. A. Johnsen said that the X-radiograms show that the 7 oxygen atoms of the combined water are not symmetrically oriented in the molecule. E. Terlandy discussed the inner structure of the crystals.

Ferrous sulphate forms solid soln. and is probably **isomorphous** with the sulphates of copper, magnesium, zinc, cadmium, vanadium, chromium, manganese, iron, cobalt, and nickel—*vide infra*. G. Agde and H. Barkholt studied the solid soln. of copper and ferrous sulphates; and E. Dittler, overgrowths of the heptahydrate with that of cobalt sulphate. A. Carnot observed that manganese can replace iron in isomorphous admixture, as in the mineral *luckite*. V. R. von Zepharovich found that the crystals of heptahydrated ferrous sulphate are isomorphous with the corresponding salt of magnesium, and in the impure Swedish mineral, *botryogene*, of J. Blaas, and J. Hockauf, magnesium replaces part of the iron in solid soln.

V. R. von Zepharovich found that isomorphous admixtures with 20 per cent. of magnesium salt have the axial ratios, $a:b:c=1.1814:1:1.5428$, and $\beta=104^\circ 19.5'$; and with 40 per cent. of magnesium salt, $1.1799:1:1.5434$, and $\beta=104^\circ 26'$ —see Fig. 641. W. Stortenbeker's study of the solid soln. of the two salts is summarized in Fig. 641.

O. Lehmann described a different modification of the crystals of the heptahydrate which were produced by cooling a hot, acidified, aq. soln. of the heptahydrate. The crystals of the heptahydrate are **dimorphous**. E. Mitscherlich found that the crystals obtained by crystallization from a soln. of ferrous sulphate at 80° , or by boiling the crystals of the heptahydrate with alcohol, are probably rhombic, and W. Haidinger supposed the eight-sided prismatic crystals so obtained were hemiheptahydrated. G. H. O. Volger, and J. A. Krenner established the existence of a labile, rhombic form of the heptahydrate, which occurs in nature as the mineral *tauriseite*—*vide supra*. The rhombic heptahydrate is said to be obtained from the aq. soln. at a temp. a little above 0° , and L. de Boisbaudran obtained it by seeding a soln. of the heptahydrate with a crystal of heptahydrated magnesium, zinc, or nickel sulphate. W. Stortenbeker said that the rhombic crystals are more soluble than the monoclinic form; and J. W. Retgers, that their sp. gr. is less. J. W. Retgers also observed that the crystals of the solid soln. with a high proportion of magnesium sulphate, are rhombic—Fig. 641.

L. de Boisbaudran found that the crystals of the hexahydrate are monoclinic, possibly isomorphous with the corresponding nickel salt; he could not prepare a tetragonal hexahydrate. J. C. G. de Marignac observed that the pentahydrate furnishes pinacoidal crystals belonging to the triclinic system. The crystals have the axial ratios, $a:b:c=0.5962:1:0.5770$, and $\alpha=81^\circ 23'$, $\beta=110^\circ 28'$, and $\gamma=105^\circ 33'$, and they are isomorphous with the corresponding copper and manganese sulphates; L. de Boisbaudran studied the isomorphism of the crystals of the pentahydrate with those of the corresponding copper sulphate. E. Mitscherlich obtained prismatic crystals of the tetrahydrate, which, according to J. C. G. de Marignac, are monoclinic prisms with the axial ratios, $a:b:c=0.4373:1:0.5833$, and $\beta=91^\circ 3'$. R. Scharizer gave for the monoclinic crystals of the tetrahydrate, $a:b:c=0.43797:1:0.58715$, and $\beta=89^\circ 29'$. The (010)-cleavage is distinct. H. V. Regnault, and P. A. von Bonsdorff said that the crystals are isomorphous with the corresponding manganese salt. C. F. Rammelsberg described a rhombic modification of the tetrahydrate; and the subject was discussed by E. S. von

FIG. 641.—The Specific Gravities of Solid Solutions of Magnesium and Ferrous Sulphates.

Fedoroff, and P. Groth. W. Stortenbeker observed that the tritaoctohydrate exists only in isomorphous admixture with the monoclinic cadmium salt. R. Scharizer said that the monohydrate, ferropallidite, probably occurs in monoclinic crystals isomorphous with kieserite, $\text{MgSO}_4 \cdot \text{H}_2\text{O}$; and J. A. Krenner gave the axial ratios, $a : b : c = 0.9544 : 1 : 0.8999$.

The **specific gravity** of anhydrous ferrous sulphate was found by E. Filhol to be 2.841, but this value is too low since L. Playfair and J. P. Joule gave 3.138, and and 3.48 at 4° ; and T. E. Thorpe and J. I. Watts, 3.346 at 15° —the best representative value is 3.30. The sp. gr. of the monoclinic crystals of the heptahydrate was determined by P. van Muschenbroek, E. Günther, and many others. R. Boyle gave 1.88; L. Playfair and J. P. Joule, 1.857, and at 4° , 1.8889; E. Filhol, 1.904; H. Schiff, 1.884; H. J. Buignet, 1.902; S. Holker, 1.851 at 15.5° ; C. Pape, 1.9854 at 16° ; J. W. Retgers, 1.898 at $18^\circ/4^\circ$, and 1.899 at $15^\circ/4^\circ$; H. G. F. Schröder, 1.881 to 1.897; F. Fränckel, and R. Scharizer, 1.89; W. C. Smith, 1.896; J. L. Andrae, 1.8988 at $11.4^\circ/4^\circ$; 1.8989 at $15.1^\circ/4^\circ$; and 1.8959 at $37.6^\circ/4^\circ$; and E. Moles and M. Crespi, 1.895 at $25^\circ/4^\circ$. L. Michel gave 1.95 for the sp. gr. of melanterite, and J. Janowsky, 1.79. J. W. Retgers calculated the sp. gr. of the rhombic form of the heptahydrate to be 1.875 by extrapolation from observations on the solid soln. with magnesium sulphate, Fig. 641. E. S. Larsen gave 2.2 for the sp. gr. of the pentahydrate. T. E. Thorpe and J. I. Watts found the sp. gr. of the tetrahydrate to be 2.227 at 15° ; R. Scharizer, 2.2775; E. Moles and M. Crespi, 2.293 at $25^\circ/4^\circ$; and F. Fränckel, 2.277. C. Pape found the sp. gr. of the trihydrate to be 2.268 at 16° ; and T. E. Thorpe and J. I. Watts gave 2.773 at 15° for the sp. gr. of the dihydrate. L. Playfair and J. P. Joule gave 3.047 for the sp. gr. of the monohydrate; E. Moles and M. Crespi, 2.970 at $25^\circ/4^\circ$; and for ferropallidite, J. Donau, and R. Scharizer gave 3.083 at 20° ; and J. A. Krenner, 3.034. The **molecular volume** of the anhydrous salt was estimated by T. E. Thorpe and J. I. Watts; H. H. Stephenson gave 48.5; and 147.5 for the heptahydrate. Estimates were also made by F. Ephraim and P. Wagner, and T. E. Thorpe and J. I. Watts. H. Schiff estimated that a gram of the water of crystallization in the heptahydrate occupies 0.72 c.c.; and E. Moles and M. Crespi estimated that the mol. vol. of each of the first 3 mols. of water lost by the heptahydrate is 16.3, and of the next 3, 13.4. H. G. K. Westernbrink calculated the ratio—volume of unit cell: the number of contained molecules to be 241.4 \AA^3 . The **molecular contraction** which occurs when the anhydrous salt is formed from its elements was calculated by H. H. Stephenson, I. I. Saslawsky, N. Schiloff and L. Lepin, and J. N. Rakshit; for the heptahydrate, by L. de Boisbaudran, J. J. Saslawsky, J. N. Rakshit, and A. Balandin; and for the tetrahydrate, dihydrate, and monohydrate, by J. N. Rakshit.

Observations on the sp. gr. of aq. soln. of ferrous sulphate were made by G. Agde and H. Barkholt, P. Barbier and L. Roux, F. Flöttmann, G. Charpy, A. Heydweiller, E. Klein, J. Königsberger, J. G. MacGregor, W. Manchot and co-workers, W. W. J. Nicol, G. Quincke, A. Hauke, G. Piaggese, H. Schiff, H. Sentis, C. Tissier, J. Thomsen, and I. Traube. G. T. Gerlach gave for the sp. gr. of soln. with the following percentage proportions of the heptahydrate, at 15° :

$\text{FeSO}_4 \cdot 7\text{H}_2\text{O}$.	1	5	10	15	20	25	30	35	40 per cent.
Sp. gr..	1.005	1.0267	1.0537	1.0823	1.1124	1.1430	1.1738	1.2063	1.2391

and for soln. with the following proportions of the anhydrous salt, at $18^\circ/4^\circ$:

FeSO_4 .	0.1386	0.1708	0.2212	0.3614	0.5240	0.6921	0.8668	0.9878 per cent.
Sp. gr..	1.00000	1.000035	1.00091	1.00233	1.00388	1.00551	1.00791	1.00832

E. Wiedemann discussed the vol. changes which occur when the soln. is heated. J. N. Rakshit gave for soln. with p per cent. $\text{FeSO}_4 \cdot 7\text{H}_2\text{O}$, at $10^\circ/20^\circ$ to $60^\circ/20^\circ$:

		10°	20°	30°	40°	50°	60°
Sp. gr.	$p = 1^\circ$	1.00780	1.00600	1.00330	0.99980	—	—
	$p = 5^\circ$	1.02980	1.02772	1.02375	1.02015	1.01620	1.01160
	$p = 10^\circ$	1.05900	1.05620	1.05200	1.04828	1.04400	1.03936
	$p = 20^\circ$	1.11880	1.11540	1.1110	1.10720	1.10300	1.09820

P. F. Gaehr represented the relation between the sp. gr., D , and the percentage composition, C , by $\log D = aC$, where a is a constant. H. Schiff gave an interpolation formula for soln. with p per cent. of $\text{FeSO}_4 \cdot 7\text{H}_2\text{O}$, sp. gr. $= 1 + 0.005175p + 0.043043p^2 - 0.07682p^3$ at 17.2° ; and J. G. MacGregor gave for the sp. gr. at 20° , $D = 0.99827 + 0.0099486p$, where p denotes the per cent. of FeSO_4 . The contraction which occurs when the heptahydrate is dissolved in water was studied by G. Charpy, I. Traube, L. Playfair and J. P. Joule, C. Tissier, R. Broom, H. Schiff, and G. T. Gerlach. J. N. Rakshit found for the contraction δv per mol. which occurs on dissolving p per cent. of the heptahydrate in water:

		10°	20°	30°	40°	50°	60°
δv	$p = 1^\circ$	34.3	35.1	19.7	5.3	—	—
	$p = 5^\circ$	19.8	19.6	11.7	4.5	3.8	4.3
	$p = 10^\circ$	20.4	18.0	13.3	10.2	8.9	8.9
	$p = 20^\circ$	16.3	14.3	11.7	10.1	9.7	9.4

E. Sonstadt observed that there is a contraction when crystals of the heptahydrate are added to a sat. soln. of ferrous sulphate, and this is attributed to adsorption. I. Traube discussed the molecular solution volume; A. Taffel, the temp. of maximum density; and H. Groshans, the density number.

The **hardness** of melanterite is said to be 2.0 on Mohs' scale. J. C. Graham found the coeff. of **diffusion** of 2 to 5 per cent. soln. of ferrous sulphate, in water at 14° to 16° , to be 0.338 per sq. cm. per day. Observations on the subject were also made by C. L. Wagner, R. E. Liesegang, and J. J. Coleman. J. Dewar found that when the heptahydrate is subjected to a high press., it exhibits **plastic flow**, as if it were a viscous fluid. Observations on the **surface tension** of aq. soln. were made by J. L. M. Poiseuille, H. Sentis, S. Oka, and C. Forch. The following observations on the surface tension, σ dynes per cm., and the **specific cohesion**, a^2 per sq. mm., at 15° to 18° , are due to A. Brümmer, H. Stocker, and G. Meyer and H. Stocker. The soln. contain the percentage proportions of FeSO_4 indicated. Those marked by an asterisk are by A. Brümmer, and the others, by H. Stocker, also contained 0.67 vol. per cent. of H_2SO_4 :

FeSO_4	0.00	3.647*	7.181*	11.661*	15.62	17.906*
σ	72.52	68.67	67.36	69.34	74.75	76.55
a^2	145.24	132.60	125.73	123.80	128.04	128.54

C. Brunner could detect no evidence of any action by a magnetic field on the capillary ascent of the aq. soln. Z. H. Skraup studied the capillary movements in filter-paper; and J. G. F. Druce, and E. W. Washburn, the crawling of the soln. on the walls of the containing vessel.

L. Playfair and J. P. Joule gave 0.000072 for the coeff. of cubic **thermal expansion** of the heptahydrate; and J. L. Andreae, 0.000066 between 14° and 38° . E. Wiedemann added that the heptahydrate expands regularly up to its m.p., 65° , and with further heating there is an abrupt expansion when the salt fuses. The thermal expansion of aq. soln. of the salt can be calculated from the data given above. C. H. Lees found the **thermal conductivity** of the heptahydrate to be 0.0013 to 0.0014 cal. per cm. per degree per second at 15° . C. Pape was unable to obtain satisfactory data for the **specific heat** of the anhydrous salt because it oxidized so readily when heated; for the heptahydrate, between 25° and 100° , he obtained 0.357 for the sp. ht.; H. Kopp gave 0.346 between 18.5° and 46.5° ; C. Forch and P. Nordmeyer, 0.239 between -190° and 14° ; whilst F. G. Jackson obtained 0.292 between 22° and -78.4° ; 0.234 between 22° and -190° ; and 0.182 between -78.4° and -190° . L. Rolla and L. Accame found the molecular heat of the heptahydrate to be 92.147, between 0° and 18° , and of the tetrahydrate, 63.587, a difference of 28.56 for the loss of 3 mols. of water. C. Pape gave 0.247 for the sp. ht. of the trihydrate; but oxidation prevented him determining the sp. ht. of the monohydrate. J. Thomsen found the sp. ht. of a 4.1 per cent. soln.

to be 0.951 at 18°; and G. Agde and H. Holtmann found, between 25° and 45°, for soln. of the percentage composition :

FeSO ₄	. 1	5	10	20	25	35	45	55	65 per cent.
Sp. ht.	. 0.999	0.945	0.910	0.860	0.840	0.802	0.767	0.732	0.702

and the results for the ternary system, ferrous sulphate, sulphuric acid, and water between 25° and 45°, are summarized in Fig. 642.

E. Greulich represented the **thermal decomposition** of ferrous sulphate in the absence of air, by the equation : $2\text{FeSO}_4 \rightleftharpoons \text{Fe}_2\text{O}_3 + \text{SO}_3 + \text{SO}_2$, and J. d'Ans, and G. Keppeler and J. d'Ans supposed that this reaction progresses in two stages : $6\text{FeSO}_4 \rightleftharpoons \text{Fe}_2(\text{SO}_4)_3 + 2\text{Fe}_2\text{O}_3 + 3\text{SO}_2$; and $\text{Fe}_2(\text{SO}_4)_3 \rightleftharpoons \text{Fe}_2\text{O}_3 + 3\text{SO}_3$; or $2\text{FeSO}_4 + 2\text{SO}_3 = \text{Fe}_2(\text{SO}_4)_3 + \text{SO}_2$, or else, if a basic sulphate is formed, $2\text{FeSO}_4 + \text{SO}_3 \rightleftharpoons \text{Fe}_2\text{O}_3 \cdot 2\text{SO}_3 + \text{SO}_2$. The dissociation pressure, P cm., where $P = p_{\text{SO}_3} + p_{\text{SO}_2} p_{\text{O}_2}$, at different temp. is :

	235°	376°	482°	614.5°	645°	698°
P	. 0.1	2.0	7.3	25.4	58.7	126.3 cm.
p_{SO_3}	. 0.05	1.0	3.6	10.8	24.9	31.2 cm.
p_{SO_2}	. 0.05	1.0	3.7	13.8	32.0	82.3 cm.

The press. attains one atm. at 680°. The partial press. of the sulphur trioxide at $T^\circ \text{K.}$ is $\log p_{\text{SO}_3} = -2691.8T^{-1} + 5.1526$. Observations on the partial press. of

FIG. 642.—The Specific Heats of Aqueous Solutions of Ferrous Sulphate and Sulphuric Acid.

10 to 20 mins. at 500° to 585°; at 590°, the vapour of sulphur trioxide appears; and at 625° to 635°, 3 per cent. is decomposed in 2 hrs. K. Friedrich and co-workers said that the end-point of the decomposition agrees with the assumption that the ferric sulphate was the last to decompose. J. d'Ans observed that in an unlimited supply of air, anhydrous ferrous sulphate begins to oxidize perceptibly about 245°, and at 440°, the reaction is rapid; and G. Keppeler added that the thoroughly-dried anhydrous sulphate decomposes rapidly at 300°. Observations were also made by E. Kothny, R. H. Bradford, A. Nemes, P. Truchot, and E. F. Kern and W. H. Walter. The thermal decomposition of anhydrous ferrous sulphate in a current of dry air was found by W. S. Landis to be first evident at 550°; the rate of decomposition is but slight at 580°; it suddenly increases rapidly at 600°, so that the reaction ceases in

FIG. 643.—The Thermal Decomposition of Anhydrous Ferrous Sulphate in Air.

about 2 hrs., and very little more decomposition occurs until the temp. is raised to 960°. H. Saito said the decomposition begins at 550°. F. Warlimont represented the reaction in a current of air by the equation : $6\text{FeSO}_4 + 3\text{O} = 2\text{Fe}_2(\text{SO}_4)_3 + \text{Fe}_2\text{O}_3$. The percentage decomposition in 3 hrs., at different temp., Fig. 643, was :

	460°	475°	500°	510°	520°	530°	550°
Decomposition .	Trace	3	12	20	40	80	100 per cent.

H. H. Willard and R. D. Fowler discussed the separation of the metals by the differences in the rates of the thermal decomposition of their sulphates.

P. A. von Bonsdorff observed that the crystals of the heptahydrate effloresce in air to form a white powder. F. Fränckel found that the heptahydrate obtained by adding alcohol to a sat. soln. of ferrous sulphate loses some water in a few hours, but R. de Forcrand found the loss at 15° was negligible with the powdered salt. R. de Forcrand observed that the tetrahydrate did not effloresce in air at 15°, but it does so over conc. sulphuric acid; and R. de Forcrand, and D. Florentin found that the monohydrate does not effloresce in air, that it is non-hygrosopic in air, and does not oxidize in air. R. Scharizer found that the first 3 mols. of water are lost from the heptahydrate in 24 hrs. to 3 weeks, dependent on the grain-size of the material; 3 other mols. are lost very slowly and the transformation into the monohydrate occupies over a year. J. B. Macintosh also noticed that melanterite passes into the monohydrate on exposure to air, and that the change is accompanied by some oxidation. W. Müller-Erzbach observed that over conc. sulphuric acid, at 14° to 22°, the heptahydrate loses 3 to 4 mols. of water; and R. de Forcrand obtained the tetrahydrate in this manner after 3 days' exposure at 15°; R. Scharizer added that the monohydrate is formed after 13 weeks' exposure. J. F. Liverseege observed that when the heptahydrate was heated in a water-oven for 90 minutes, it left a residue containing 82.5 per cent. of FeSO_4 , and 1 per cent. insoluble in water. J. Pritzker and R. Jungkunz found that 6 mols. of water are removed when the heptahydrate is heated in xylene. T. Graham observed that in vacuo, over phosphorus pentoxide, the heptahydrate lost 5.48 mols.; and in the high vacuum of the cathode light, over phosphorus pentoxide, F. Krafft, and A. Adolphi observed a loss of nearly 6 mols. of water. R. Scharizer studied the rate of dehydration of the heptahydrate over conc. sulphuric acid, and unlike the case with many other hydrated sulphates, no period of induction was observed. Measurements of the **vapour pressure** of the heptahydrate were made by W. Müller-Erzbach, H. Precht and K. Kraut, R. E. Wilson, and A. H. Pareau. E. Cohen and A. W. Wisser gave for the vap. press., p mm. :

	30.67°	39.96°	44.45°	46.43°
p	21.76	39.94	52.86	59.63 mm.

and W. C. Schumb observed that the heptahydrate passes into the hexahydrate when p at 25° is 14.56 mm. E. Wiedemann made observations on this subject.

C. Pape found that the heptahydrate shows signs of dehydration at 33°, and C. Gaudefroy, at 35°; but J. L. Andreae said that no water is lost by the crystals in benzene or in methylene or ethylene iodide at 37.6°. T. Graham observed that 6 mols. of water are lost at about 115°; H. Precht and K. Kraut, in vacuo at 79°; J. B. Hannay, at 100° in air dried by sulphuric acid; E. Moles and M. Crespi, in dry air at 100° to 120°; R. de Forcrand, in hydrogen at 100°; W. Peters, in hydrogen at 115°; T. E. Thorpe and J. I. Watts, in hydrogen at 120°; A. Rosenstiehl, in hydrogen at 140°; and G. Keppeler and J. d'Ans, in hydrogen at 150° to 200°. As indicated above, the seventh mol. of water was shown by J. J. Berzelius, R. Brandes, and T. Graham to be retained rather tenaciously; E. Mitscherlich said that in air it is lost above 200°; T. Graham, above 280°; A. Ditte, and A. Adolphi, at 280° to 300°; and E. Greulich, in hydrogen at 300°. In air or hydrogen, dried by phosphorus pentoxide, J. B. Hannay said that a part of the seventh mol. proportion of water is expelled at 100°, and T. E. Thorpe and J. I. Watts, and H. Precht and K. Kraut, said that all is expelled. In the high

vacuum of the cathode light, in the presence of barium oxide, F. Krafft, and A. Adolphi found that the last mol. of water is expelled. According to J. Waltl, at higher temp., the heptahydrate decomposes with the loss of sulphur trioxide to form a basic ferric sulphate, not the normal sulphate. H. O. Hofman and W. Wanjukoff found that when heated in an open tube in dry air, 3 mols. of water are lost between 20° and 72°; another 3 mols. between 80° and 123°; between 132° and 142°, a transformation occurs; between 150° and 366°, slow oxidation

FIG. 644.—Heating Curves of Hydrated Ferrous and Ferric Sulphates.

occurs forming a basic ferric sulphate without loss of water; and between 406° and 482°, the last mol. of water is expelled, and $\text{Fe}_2\text{O}_2\text{SO}_4$ is formed. E. Moles and M. Crespi found that the first 3 mols. of water are expelled at 60° to 70°, and the next 3 mols. at 100° to 120°. R. Scharizer said that in dry air, 3 mols. of water are lost at 40°; at 60° to 80° another 3 mols. of water are expelled, and oxidation sets in, and at 100° the sulphate is oxidized to a pale yellowish-brown powder; between 100° and 160°, the material retains two-sixths, and between 160° and 300°, one-sixth of a mol. of water. The remaining half mol. of water requires a red-heat for its expulsion. H. Saito's heating curve, obtained with a thermo-balance, is indicated in Fig. 644. J. B. Hannay obtained a heating curve showing breaks corresponding with the di- and mono-hydrates. Observations were also made by K. Honda and T. Ishiware, L. Hackspill and A. P. Kieffer, M. Copisarow, K. Friedrich and A. Blickle, and K. Friedrich. E. Beutel and A. Kutzelnigg found that the heptahydrate effloresces 5.14 times as fast when illuminated by ultra-violet light, and loses 3 mols. of water in 2 hrs.

W. W. J. Nicol, and W. Müller-Erbach measured the vap. press. of aq. soln. of ferrous sulphate, and for a sat. soln., at 65°, 75°, 85°, and 95°, the former gave $p=165.7$, 259.3, and 587.8 mm. respectively. G. Tamman observed that the **lowering of the vapour pressure** of water, δp mm., with soln. containing w grms. of FeSO_4 per 100 grms. of water, is:

w	8.73	15.96	23.99	28.39	46.96	53.27
δp	6.6	11.0	16.5	20.3	43.7	49.8

G. Weidemann found that the crystals of the heptahydrate become white at about 73°, they sinter together at about 80°, and melt at about 90°. E. Wiedemann added that at the **melting-point** of the heptahydrate, the liquefaction is only partial, for the salt is more or less transformed into a lower hydrate; W. A. Tilden found that the break in the solubility curve at 64° corresponds with the m.p. of the heptahydrate. The **lowering of the freezing-point** of aq. soln. by ferrous sulphate was observed by C. Blagden, L. C. de Coppet, F. M. Raoult, N. Sasaki, N. Tarugi and W. Manchot, G. Bombardini, L. Kahlenberg, and F. Fränckel. W. Kistiakowsky found that with soln. containing 0.977, 1.458, 2.83, and 5.63 grms. of FeSO_4 in 100 grms. of water, the f.p. were lowered respectively 0.15°, 0.23°, 0.415°, and 0.725°; and the mol. lowering of the f.p. ranged from 1.036 to 1.268. R. de Forcrand estimated the **boiling-point** of the heptahydrate to be 118.3°, of the tetrahydrate, 118.5°, and of the monohydrate, 300°. G. T. Gerlach found the b.p. of soln. with 17.7, 34.4, 50.4, and 53.4 grms. of FeSO_4 per 100 grms. of water to be respectively 100.5°, 101.0°, 101.5°, and 101.6°. Observations on the **raising of the boiling-point** were made by W. W. J. Nicol, and N. Tarugi and G. Bombardini. L. Kahlenberg found that with soln. containing 3.245, 15.810, 26.645, and 35.35 grms. of FeSO_4 per 100 grms. of water, the raisings of the b.p. were respectively 0.093°, 0.412°, 0.713°, and 1.099°.

E. Greulich calculated 189.5 Cals. for the **heat of formation** of anhydrous

ferrous sulphate between 316° and 514° . J. Thomsen gave for the heat of formation of the solid heptahydrate, $(\text{Fe}, \text{O}_2, \text{SO}_2, 7\text{H}_2\text{O}) = 169.04$ Cals.; and in aq. soln., $(\text{Fe}, 4\text{O}, \text{S}, \text{Aq.}) = 236.283$ Cals.; $(\text{Fe}, \text{O}, \text{SO}_3, \text{Aq.}) = 93.2$ Cals.; $(\text{Fe}, \text{H}_2\text{SO}_4, \text{Aq.}) = 24.84$ Cals. with the escape of H_2 gas; $(\text{Fe}(\text{OH})_2, \text{H}_2\text{SO}_4, \text{Aq.}) = 24.92$ Cals. For the heat of formation in dil. soln., E. Greulich gave 234.9 Cals. R. de Forcrand gave $\text{FeSO}_4 \cdot 4\text{H}_2\text{O} + 3\text{H}_2\text{O} = \text{FeSO}_4 \cdot 7\text{H}_2\text{O}_{\text{solid}}$, 34.902 , 5.922 , and 1.632 Cals. according as gaseous, liquid, or solid water is assumed in the calculation; likewise for the solid tetrahydrate, $\text{FeSO}_4 \cdot \text{H}_2\text{O} + 3\text{H}_2\text{O} = \text{FeSO}_4 \cdot 4\text{H}_2\text{O}$, 34.92 , 5.939 , and 1.650 Cals. according as gaseous, liquid, or solid water enters into reaction; similarly for the solid monohydrate, $\text{FeSO}_4 + \text{H}_2\text{O} = \text{FeSO}_4 \cdot \text{H}_2\text{O}$, 17.023 , 7.363 , and 5.933 according as gaseous, liquid, or solid water enters into the reaction. He observed no thermochemical grounds for assuming the existence of the di-, tri-, penta-, or hexa-hydrates. E. Cohen and A. W. Visser calculated 1.912 Cals. per mol. of water for the heat of transformation of the tetrahydrate into the heptahydrate. Observations were also made by P. A. Favre and J. T. Silbermann, and W. P. Jorissen. J. Thomsen gave for the **heat of neutralization** of a soln. of ferrous sulphate with potassium hydroxide, $\text{FeSO}_4 + 2\text{KOH} = \text{K}_2\text{SO}_4 + \text{Fe}(\text{OH})_2 + 6.34$ Cals.; and with a soln. of barium hydroxide, 12.084 Cals. J. Thomsen gave -4.51 Cals. for the **heat of solution** of a gram of the heptahydrate in 400 grms. of water; P. A. Favre and C. A. Valson gave -4.364 Cals.; R. de Forcrand gave -4.323 Cals. for the heat of soln. of the heptahydrate; 1.599 Cals. for the tetrahydrate; and 7.538 Cals. for the monohydrate. Observations were also made by P. A. Favre and J. T. Silbermann, and T. Graham. E. Greulich calculated 12.3 Cals. for the **heat of dissociation** of anhydrous ferrous sulphate between 316° and 554° ; and values were also calculated by G. Keppeler and J. d'Ans, and J. d'Ans: $2\text{FeSO}_4 = (\text{Fe}_2\text{O}_3 + \text{SO}_3) + \text{SO}_2 + 6.1$ Cals. H. Schottky calculated values for the total and **free energy**, F , involved in the union of a mol. of ice with the hexahydrate to form the heptahydrate, and found $F = 275$ cals., and the heat of combination $Q = 200$ cals.

A. des Cloizeaux gave for the **index of refraction** of the crystals of the heptahydrate: 1.469 for red-light, 1.470 for yellow-light, and 1.478 for blue-light. M. Eroféeef gave $\alpha = 1.4681$, $\beta = 1.4748$, and $\gamma = 1.4824$ for Li-light; $\alpha = 1.4713$, $\beta = 1.4782$, and $\gamma = 1.4856$ for Na-light; and $\alpha = 1.4794$, $\beta = 1.4861$, and $\gamma = 1.4928$ for blue-light. R. Scharizer gave $\alpha = 1.533$, and $\beta = 1.535$ for the tetrahydrate. B. Wagner gave for the index of refraction, μ , at 17.5° , of soln. containing per 100 c.c.

FeSO_4	1	2	4	6	8	10	12	15	20 grms.
μ	1.33511	1.33696	1.34048	1.34393	1.34732	1.35064	1.35391	1.35871	1.36649

and A. Hauke found for a soln. with 12.74 per cent. FeSO_4 , 1.3576 for the Na-line; 1.3595 for the Tl-line; and 1.3557 for the C-line. According to F. Flöttmann, the sp. gr. of 1 per cent. soln. of ferrous sulphate are respectively 1.0092 , 1.0082 , and 1.0070 at 15° , 20° , and 25° ; and the indices of refraction for the D-line are respectively 1.33528 , 1.33490 , and 1.33443 . Observations were also made by E. Doumer, E. E. Sundwik, F. Flöttmann, and B. Walter. For soln. with up to 34 per cent. FeSO_4 , P. Bary observed a break in the concentration-refractive index curve corresponding with $\text{FeSO}_4 \cdot 7\text{H}_2\text{O}$. W. Sutherland calculated, with the μ -formula, the molecular refraction of the heptahydrate 29.7 for the A-line; J. H. Gladstone and W. Hibbert gave 28.4 . P. Barbier and L. Roux discussed the **dispersion** of soln. of different concentrations. P. Krishnamurti studied the **Raman effect**.

According to B. Franz, and R. Zsigmondy, soln. of ferrous sulphate, according to their concentration and thickness, absorb 90 to 98 per cent. of the **heat rays**. For **ultra-violet light**, *vide supra*. T. Dreisch observed with a 5 mm. layer of a soln. having 1 mol. of FeSO_4 per litre, a strong maximum in the absorption band for light of wave-length $\lambda = 0.95\mu$, and a weak maximum for $\lambda = 1.07\mu$. H. M. Vernon discussed the change of the colour of soln. on dilution or on raising the temp. J. S. Anderson studied the **absorption spectrum** of the soln. and found for the

extinction coeff., k , of soln. of a mol. of FeSO_4 per litre, with layers between 0.14 and 2 cm. thick :

λ . .	4340	4630	5470	6250	6870	7460	9000	11,750	13,000
k . .	0.22	0.14	0.058	0.080	0.16	0.25	1.26	1.39	1.14

and for soln. with C mol of FeSO_4 per litre :

$\lambda = 4530$					$\lambda = 6530$		
C	1.5	0.75	0.5		1.5	0.75	0.5
k	0.074	0.074	0.12		0.10	0.094	0.11

Observations were also made on the ultra-red visible rays by R. A. Houston, and R. A. Houston and C. Cochrane. A. Byk and H. Jaffe observed that the ultra-violet rays are also absorbed by soln. of ferrous sulphate, and that with increasing concentration, the absorption limits are displaced towards the longer wave-lengths. Thus, C. R. Crymble observed for 0.1*N*- and 0.01*N*-soln., $\lambda = 2580$ Å. for a 2 cm. layer, and $\lambda = 2180$ Å. for a 1 cm. layer. Observations were also made by G. P. Drossbach, and S. Kato.

E. A. Owen found the mol. absorption coeff. of the anhydrous sulphate for the **X-rays**, 2369.5 for $\lambda = 0.586$ Å., and 544.20 for $\lambda = 0.35$ Å., when the value for water is 55.8. J. L. Glasson studied the absorption of X-rays by the heptahydrate; and W. Ackroyd and H. B. Knowles observed that heptahydrated ferrous sulphate is only a little less transparent for the X-rays than the corresponding salts of cobalt and nickel. The absorption coeff. of aq. soln. containing 1.08, 0.54, and 0.133 mol FeSO_4 per litre were found by T. E. Aurén to be respectively 53.0, 56.5, and 58.4. Observations were also made by N. A. Schischakoff, and A. Hébert and G. Reynaud. According to H. Fricke and S. Morse, the rate of decomposition of 0.00878*M*- to 0.001*M*- FeSO_4 is linear for the same dosage of X-rays, but for increased dosages, the rate of decomposition is still linear, but the rate is halved. With a 0.000406*M*-soln. the rate of decomposition has a linear relationship to the X-ray dosage until decomposition is practically complete. With increased doses the conc. of ferrous sulphate is gradually restored to an equilibrium value about 50 per cent. of the initial one. In the first cases, the change in the rate of decomposition is shown to take place at the point where all the dissolved oxygen in the soln. has been used up. In the later stages of the decomposition, the transformation of the ferrous ions is a secondary effect due to activated water mols. produced by secondary X-ray electrons. The apparent reversal of the reaction in the last case is attributed to the interference in the soln. of a reducing substance (perhaps hydrogen dioxide). N. A. Schischakoff, and G. L. Clark and L. W. Pickett studied the subject.

K. Niederstadt observed that the heptahydrate forms a pale green powder when exposed to **radium rays**; and A. Kailan studied the action of these rays on aq. soln. of the salt. E. Ohlon observed that at the temp. of liquid air, the heptahydrate does not luminesce when exposed to **cathode rays** or to **canal rays**; and it exhibits no **thermoluminescence** when warmed to room temp. E. Wiedemann and G. C. Schmidt found that the presence of ferrous sulphate weakens the **luminescence** of many substances, thus, 1 per cent. suppresses the **photoluminescence** of zinc sulphate; but W. Arnold found that the cathodoluminescence of lithium sulphate is strengthened by ferrous sulphate. A. E. Garrett observed that when heated to 360°, ferrous sulphate emits ions. W. Zimmermann observed the **photoelectric effect** of ferrous sulphate in ultra-violet light. H. Nisi studied the **Raman effect**. E. Giebe and A. Scheibe observed no **piezoelectric effect** with the heptahydrate. For the effect of an electric field on the crystallization of the salt, *vide supra*. The **magnetic rotatory power**, or **Verdet's constant**, ω , for sat. soln. of ferrous sulphate, at 23°, in a field of about 12,050 gauss, for $\lambda = 6000$ and 8000 Å., was found by L. R. Ingersoll to be respectively $\omega = 0.0087$ and 0.0050. Observations were also made by M. E. Verdet, and O. Schönrock. F. Allison and E. J. Murphy

studied the magneto-optic properties; and W. Sucksmith, the gyromagnetic properties. The **magnetic dichroism** of soln. of ferrous sulphate in organic solvents was studied by G. Meslin. H. Hellmann and H. Zahn measured the **dielectric constant** of aq. soln. of ferrous sulphate.

E. Klein measured the **electrical conductivity** of aq. soln. of ferrous sulphate, at 18° and 26°. F. Kohlrausch and L. Holborn found the eq. conductivity, λ , and the sp. conductivity of soln. with a gram-equivalent of ferrous sulphate in v litres at 18°, and the temp. coeff., α , of the soln. between 18° and 22°, to be:

v	.	.	.	2	1	0.50	0.33	0.28
λ	.	.	.	30.8	25.8	19.5	15.37	13.21
Sp. cond.	.	.	.	154	258	390	461	470 mhos
α	.	.	.	0.0218	0.0218	0.0223	0.0231	0.0243

L. Kahlenberg found similarly for the eq. conductivity, λ , and H. Vierling for the mol. conductivity, μ , at 25°:

v	.	1	4	8	16	32	128	256	1024	2048
λ	{	16.3	23.0	28.1	31.4	36.3	47.2	52.1	59.5	62.0
	95°	60.6	89.2	103.5	125.5	104.2	211.5	250.3	319.9	413.1
μ	.	—	56	84	96	118	165	189	264	300 (315)

where the number in brackets represents the value after 3 minutes, whereas the other number refers to a soln. one minute old. L. Kahlenberg also gave at 0°, $\lambda=64.9$ for $v=8192$. W. Manchot gave $\mu_{\infty}=230$ mhos. Observations on the conductivity of aq. soln. were also made by O. Mustad, F. Foerster, R. C. Wells, N. Tarugi and G. Bombardini, J. Trötsch, N. Sasaki, C. L. Wagner, and N. Sasaki. E. Klein found that the oxidation of the soln. by air has but little effect on the conductivity. H. Vierling examined the effect of hydrogen and oxygen in the presence and absence of platinum, and of sulphuric acid. F. Neesen observed that a magnetic field had no perceptible effect on the conductivity, and the subject was also studied by G. Berndt. The percentage **degree of ionization**, α , of the soln. with a mol of the salt in v litres, at 18°, was found by W. Manchot to be:

v	.	15.6	33.3	80	160	640	1280	2560	5120
α	.	38.5	45.9	54.6	66.1	80.7	87.0	97.6	97.6 per cent.

Observations were also made by N. Tarugi and G. Bombardini. The ionization factor, $i=1.15$, 10—was found by F. Fränkel for soln. with C grms. of FeSO_4 per 100 grms. of water, at 0°:

C	.	.	.	1.0156	2.5974	5.1684	7.7369	13.483
i	.	.	.	1.39	1.17	1.03	1.00	0.984

Observations were also made by W. Manchot, W. Kistiakowsky, L. Kahlenberg, S. Arrhenius, and N. Tarugi and G. Bombardini. K. Szalagyi found the **transport number** of the Fe^{++} -ion to be 0.302 at 20°.

W. Manchot and co-workers calculated values for the **solvation or hydration** of the salt in aq. soln., i.e. the number of mols, n , of water bound up with a mol of FeSO_4 at 25°, and obtained for soln. with 0.7256 and 1.4634 mols of FeSO_4 per litre, $n=26.7$ and 21.7 respectively. J. H. Walton and A. Brann studied the relation between the rate of crystallization and the degree of hydration of the molecules of the solute. According to J. H. Long, the **degree of hydrolysis** of 0.5N- FeSO_4 at 85° is 0.033 per cent. A. Krause found the **H⁺-ion concentration** of N- FeSO_4 to be $p_{\text{H}}=3.5$; the electrometric titration for the determination of the acidity of the soln. was discussed by M. Koenig, B. Kamiensky, and T. Haczko. G. S. Tilley and O. C. Ralston said that hydrolysis begins with a H⁺-ion conc. 10^{-9} , or a OH⁻-ion conc. of 10^{-5} , but M. R. Thompson said that the ferrous salts begin to hydrolyze in a faintly acidic soln. with p_{H} probably 5 or 6, rather than in a faintly alkaline soln. with $p_{\text{H}}=9$, as suggested by G. S. Tilley and O. C. Ralston. P. A. von Bonsdorff found that a soln. free from ferric salts, and boiled with iron turnings does not affect the colour of blue-litmus, and only when the soln. is

oxidized by air does a blue coloration appear. C. C. Ahlum also found that the aq. soln. of ferrous sulphate is neutral to methyl orange. R. Saxon studied the electrolysis of soln. of the sulphate; and N. Kameyama and K. Takahashi, the electro-oxidation of the salt.

L. Riéty studied the potential of a soln. of ferrous sulphate flowing through a capillary tube under a press. of 25 atm. The **electromotive force** of various cells with a soln. of ferrous sulphate as one of the electrolytes was measured by J. A. Atanasiu and V. Stefanescu, W. D. Bancroft, B. Neumann, K. F. Ochs, and T. Swensson; M. Krieg studied the **polarization** of platinum in soln. of ferrous sulphate; and P. Baumann found the **decomposition voltage** of $0.2N\text{-FeSO}_4$ to be 1.3 volts; and the subject was studied by H. Vierling. The electrolysis of soln. of ferrous sulphate from the point of view of the preparation of iron has been previously discussed. The anodic oxidation of the liquid during the electrolysis, and the deposition of hydrated ferric oxide was discussed by H. Buff, M. Berthelot, A. G. Betts, A. Brochet and J. Petit, A. Klemenc, J. H. Paterson, C. F. Schönbein, and Z. Karaoglanoff. According to M. M. Tichwinsky, when a 30 per cent. soln. of ferrous sulphate is electrolyzed between iron electrodes by a very weak current in the dark, a soln. is obtained in the course of a month or two which differs considerably from the ordinary soln. of ferrous salts. Its colour is more intensely green, somewhat like that of nickel sulphate, and on exposure to light, it deposits a green solid, which may be preserved for an indefinite period if air be excluded. Analysis of the soln. showed it to contain twice as much iron for a given quantity of sulphuric acid as is contained in ferrous sulphate. It therefore contains the basic salt, ferrous oxysulphate, $\text{FeO} \cdot \text{FeSO}_4$, which decomposes on exposure to light with the deposition of ferrous hydroxide which is coloured green by some ferrous sulphate carried down with it, and consequently the precipitate becomes paler in colour as it is washed. T. von Grotthus, and F. Braun studied the decomposition of an electrolyte in a narrow crack through which a current passes; F. Braun called the phenomenon electrostenolysis. It was also investigated by R. de Muynk. A. Schükareff observed that if the anode is in a magnetic field of 2000 to 7000 gauss during the electrolysis of a soln. of ferrous sulphate between platinum electrodes, the current between the plates is enhanced, but not so if the cathode be in the magnetic field.

M. Faraday observed that the paramagnetism of anhydrous ferrous sulphate is not perceptible at -45° . The **magnetic susceptibility** of the solid was found by J. Königsberger to be $\chi = 37 \times 10^{-6}$ mass unit at 22° ; G. Meslin gave $\chi = 51 \times 10^{-6}$; and G. Berndt, $\chi = 69.4 \times 10^{-6}$. W. Finke gave for the three crystal axes, *a*, *b*, and *c*, respectively, 84.32×10^{-6} , 78.74×10^{-6} , and 76.20×10^{-6} . With a field of about 2000 gauss, K. Honda and T. Ishiwara, and T. Ishiwara gave for the anhydrous salt:

	-162.8°	-56.3°	8.5°	88.0°	286.3°	404.3°	642.3°
$\chi \times 10^6$	177.0	97.5	76.9	74.2	39.5	32.6	24.0

and H. K. Onnes and co-workers, with a field of 10,000 to 17,000 gauss, obtained:

	-258.7°	-253.0°	-203.3°	-202.7°	-195.8°	-103.5°	17.1°
$\chi \times 10^6$	335	402	227.3	215.1	200.4	107.2	67.6

The results were found by H. K. Onnes and co-workers, T. Ishiwara, and K. Honda and T. Ishiwara to be in general agreement with the relation $\chi(T + \theta) = \text{constant}$ —*vide supra*, the magnetism of iron. The effect of temp. on the magnetic susceptibility of the anhydrous salt was also studied by G. Foëx, and L. C. Jackson whose results for the reciprocal of the mol. magnetic susceptibility at different temp., $^\circ\text{K}$., are indicated in Fig. 645. W. Sucksmith studied the gyromagnetic effect.

The paramagnetism of the heptahydrate was studied by M. Faraday, T. J. Seebeck, and J. Plücker and A. Beer. C. B. Greiss observed some remanent magnetization, but C. Matteucci observed none. G. Berndt detected no hysteresis at

200 gauss. The behaviour of crystals of the heptahydrate when suspended in a magnetic field was studied by M. Faraday, J. Plücker and A. Beer, and H. E. Armstrong and E. H. Rodd. Observations on the magnetic susceptibility were made by J. Plücker, J. S. E. Townsend, G. Berndt, G. Meslin, L. C. Jackson, G. Falckenberg, M. H. Belz, S. Meyer, J. Königsberger, and G. Wiedemann. According to W. Finke, the vol. susceptibility of the heptahydrate in air, at 20°, in a field of 7800 gauss in the direction of the *a*-axis is 84.32×10^{-6} ; in the direction of the *b*-axis, 78.74×10^{-6} ; and in the direction of the *c*-axis, 76.20×10^{-6} . S. Meyer said that the magnetic susceptibility is independent of the field-strength between 600 and 10,000 gauss. K. Honda and T. Ishiware, and T. Ishiware gave for the susceptibility of the heptahydrate at different temp., and a field-strength of about 2000 gauss :

FIG. 645.—The Reciprocal of the Magnetic Susceptibility of Ferrous Sulphates.

	-173.6°	-109.7°	-53.5°	2.3°	103.7°	508.8°	930.9°
$\chi \times 10^6$	122.7	76.6	56.8	44.5	35.1	14.1	5.1

and H. K. Onnes and co-workers observed with a field-strength of 5000 to 14,000 gauss :

	-259.17°	-256.09°	-254.37°	-252.77°	-208.86°	-195.65°	16.5°
$\chi \times 10^6$	757.2	641.6	589.7	555.4	186.1	154.5	41.46

The relation χT ranges from 11,110 at -258.3° to 12,390 at 19.3° . The subject was studied by E. Oosterhuis, C. A. Crommelin, and R. Gans. B. Cabrera and co-workers examined the influence of the water of hydration on the susceptibility of the salt.

M. Faraday studied the paramagnetism of the aq. soln. of ferrous sulphate. C. Matteucci observed no evidence of remanent magnetization. A. Quartaroli observed that a soln. with 3.17 grms. of Fe per litre is neutral with respect to magnetization for the paramagnetism of the salt then neutralizes the diamagnetism of the water. The changes in the form of the surface of the soln. in a magnetic field were studied by J. Plücker, J. Jamin, R. W. Roberts and co-workers, A. Quartaroli, W. Rathert, and A. Righi. Observations on the magnetism of the aq. soln. were made by A. Arndsten, E. Becquerel, I. Borgmann, H. W. Eaton, A. Heydweiller, J. Plücker, T. Wöhner, G. Wiedemann, and O. Wylach. G. Jäger and S. Meyer found the magnetic susceptibility, χ mass unit, to be 93×10^{-6} at 18° ; J. S. E. Townsend gave 75×10^{-6} at 10° ; G. Quincke, 82×10^{-6} at 19° ; O. Liebknecht and A. P. Wills, 84×10^{-6} at 18° ; J. Königsberger, 75×10^{-6} at 22° ; G. Falkenberg, 73.3×10^{-6} ; and K. Honda and T. Ishiware, 74.2×10^{-6} at 19.3° . P. Weiss and C. A. Frankamp found for soln. of the following percentage composition, at 12.6° to 18.6° :

FeSO ₄	0.488	0.512	0.885	1.229	3.810	12.100	20.700
$\chi \times 10^6$	-0.3210	-0.3060	0.00141	0.2724	2.3580	9.0100	15.8700

The raising of the susceptibility of the heptahydrate as it passes into aq. soln. was observed by G. Wiedemann, and A. Heydweiller to be small; but J. Königsberger observed a very marked increase. G. Piaggese gave for the influence of temp. with the percentage concentration, *C*, and field-strength, *H* :

	<i>C</i> = 20.52 ; <i>H</i> = 3600			<i>C</i> = 12.95 ; <i>H</i> = 4100			<i>C</i> = 8.43 ; <i>H</i> = 7460		
	24.0°	69.5°	85.5°	16.6°	60.5°	86.8°	23.5°	61.3°	83.3°
$\chi \times 10^6$	24.275	23.077	20.203	12.525	11.207	10.401	6.812	6.478	5.770

The effect of temp. was also measured by E. Becquerel, H. Breternitz, P. Curie, G. Falckenberg, G. Jäger and S. Meyer, L. Lombardi, G. Meslin, P. Theodorides, A. E. Oxley, R. Oppermann, G. Piaggese, G. Quincke, P. Pascal, R. H. Weber, G. Wiedemann, and E. Wilson; the effect of concentration, by G. Falckenberg, G. Jäger and S. Meyer, J. Königsberger, R. Oppermann, A. Quartaroli, J. S. E. Townsend, and P. Weiss and C. A. Frankamp; the influence of the field-strength, by A. Arndtsen, G. Falckenberg, A. Heydweiller, G. Jäger and S. Meyer, J. Königsberger, L. Lombardi, P. Pascal, J. S. E. Townsend, T. Wähner, R. H. Weber, and O. Wylach; and the influence of changes in the frequency of the alternating current, by G. Falckenberg. The results were calculated to express mol. susceptibilities by A. Quartaroli, A. Heydweiller, O. Liebknecht and A. P. Wills, and P. Philipp; and the atomic susceptibilities, by P. Weiss and C. A. Frankamp, O. Liebknecht and A. P. Wills, and R. H. Weber. B. Cabrera and co-workers obtained for the mol. susceptibilities, at $20\cdot3^\circ$, $-195\cdot7^\circ$, and $-208\cdot4^\circ$ the respective values $0\cdot011917$, $0\cdot044612$, and $0\cdot053231$; and for Curie's relation, $3\cdot498 = \chi(T+1\cdot1^\circ)$. K. Honda and T. Ishiware calculated for the **magnetic moment** of anhydrous ferrous sulphate, $4\cdot74 \times 10^{-20}$; whilst H. K. Onnes and E. Oosterhuis gave $4\cdot72 \times 10^{-20}$. R. Gans, and L. Pauling and M. L. Huggins calculated the **magneton number** of the heptahydrate to be $26\cdot09$; and values for the salt in aq. soln. were calculated by B. Cabrera and co-workers, A. Quartaroli, R. H. Weber, P. Weiss, and P. Weiss and C. A. Frankamp. D. Samuracas found that the crystallization from aq. soln. is accelerated in a magnetic field.

The chemical properties of ferrous sulphate.—According to J. A. Arfvedson, anhydrous ferrous sulphate is reduced to iron disulphide when it is heated to redness in a current of **hydrogen**, and H. Rose observed that ferrous sulphide is formed. If the hydrogen is under a press. of 200 atm., W. Ipatéeff and A. Kisseleff found that ferrous sulphide, and microcrystalline ferrous oxide are formed, and at 260 atm., and 350° , only crystalline ferrous sulphide. At a high enough temp., the sulphate is reduced by hydrogen to metallic iron. G. Keppeler and J. d'Ans observed that the monohydrate passes into the anhydrous salt when heated at 200° in a current of hydrogen. S. Miyamoto found that the sulphate is reduced by hydrogen in the silent discharge. W. Ipatéeff and co-workers, and J. H. Weibel studied the reduction of ferrous sulphate in aq. soln. by hydrogen under press., and found that at 330° and 200 atm., ferrous sulphide and ferrous oxide are formed, whilst at 350° and 260 atm., crystalline ferrous sulphide alone is formed. For the reduction of ferric salts by nascent hydrogen, *vide infra*, the action of some metals on the soln. B. Neumann detected no reduction of the aq. soln. by hydrogen in the presence of platinum.

R. Brandes, and J. d'Ans observed that when the anhydrous salt is exposed to **air**, it readily takes up moisture, and in moist air, the heptahydrate is formed. The absorption of moisture is quicker if the ferrous sulphate is contaminated with ferric sulphate. The heptahydrate was found by P. A. von Bonsdorff to weather to a white powder on exposure to air—*vide supra*. At ordinary temp., the heptahydrate gradually acquires a brown colour on exposure to air at ordinary temp. owing to its oxidation to basic or normal ferric sulphate. The formation of a basic sulphate or sulphates was emphasized by A. Maus, R. Scharizer, and H. O. Hofman and W. Wanjukoff. The oxidation takes place more readily if the air be humid. R. Scharizer said that oxidation is of minor significance in dry air; but in moist air, the heptahydrate may liquefy in the adsorbed water, and oxidation proceeds apace. The imperfectly dried crystals also oxidize more rapidly than is the case if they have been thoroughly dried. Crystals which have been deposited from neutral soln. are more liable to aerial oxidation than crystals obtained from acidic soln. J. d'Ans, C. Baskerville and R. Stevenson, and F. Fränckel found that if the heptahydrate is of a high degree of purity, it is very much less readily oxidized in air, than is the case with the ordinary salt. P. Geiseler, and A. Piccini and F. M. Zuco observed that the crystals of the heptahydrate can be preserved

unchanged in a sealed tube for years. G. Welborn recommended the introduction of a few drops of ether in the tube before sealing; H. Hager, a little camphor wrapped up in paper; and A. Gawalowsky, a side tube containing a little alkaline soln. of pyrogallol and glass wool. H. Hager emphasized the need for completely removing the mother-liquor from the heptahydrate crystals; and R. de Forcrand recommended powdering the crystals, and repeatedly drying the powder by pressure between folds of filter-paper; he said that the product is quite stable in air at 15°. G. Ruspini discussed the preservation of the heptahydrate. P. Chastaing observed that the speed of oxidation of the powdered heptahydrate is increased by exposure to light, and that the red rays are more active than the violet. F. Thomas found that after exposing a soln. of ferrous sulphate to light and oxygen, the oxygen absorbed was relatively:

Red	Yellow	Green	Violet	Darkness
71	74	80	76	72

H. Fricke studied the influence of X-rays on the oxidation of aq. soln. of ferrous sulphate, and the results are independent of the wave-length.

R. Scharizer observed that in **oxygen**, the heptahydrate is readily oxidized to hygroscopic ferric sulphate; D. Tommasi also noted the tendency of the heptahydrate to oxidize in detonating gas. When the anhydrous salt is moderately heated in air, oxidation occurs, and the so-called *burnt or calcined green vitriol* is produced, and the product is considered to be a basic ferric sulphate, $\text{Fe}_2\text{O}(\text{SO}_4)_2$. The thermal decomposition of ferrous sulphate in a limited supply of air, and with the free access of air, has been previously discussed. The aq. soln. gradually becomes turbid on exposure to air, and a yellowish-brown basic salt is precipitated, and, according to F. Muck, the composition of the precipitate varies with the composition of the soln. This probably means that the basic salt is a hydrated ferric oxide with more or less adsorbed sulphate. R. Scharizer, and E. Manasse observed that if ferrous sulphate be warmed, oxidation is very rapid, and since, above 80°, all is present as monohydrate, it is assumed that the first stage of the oxidation involves the formation of the complex:

which breaks up into $2\text{Fe}(\text{OH})\text{SO}_4$ and water; it is also supposed that a similar intermediate product is formed in the oxidation of aq. soln. of ferrous sulphate. W. Manchot and W. Pflaum, W. Franke, and H. Wieland and W. Franke discussed the formation of complexes in the oxidation of ferrous sulphate. T. Warynsky found that aq. soln. of ferrous sulphate are fairly stable provided the water be acidulated with dil. sulphuric acid; and A. Jilek observed no oxidation at the end of 48 hrs. with soln. containing sulphuric acid. Exposure to light accelerates the rate of oxidation, and F. Thomas found that with neutral soln., the relative rates of oxidation are: in red-light, 49; in yellow-light, 52; in green-light, 54; in violet-light, 53.5; and in darkness, 50, but the rate of oxidation of the acidified soln. was too slow for measurement under the conditions of these experiments. P. Chastaing, C. E. Nurnberger, and B. K. Mukerji and N. R. Dhar also compared the rate of oxidation of soln. of ferrous sulphate in light and in darkness. F. R. Ennos found that the rate of oxidation of the aq. soln. is proportional to the partial press. of the oxygen; and, according to C. G. MacArthur, the rate is reduced by the addition of conc. soln. of inert, soluble salts—*e.g.*, the chlorides and sulphates of sodium, potassium, or magnesium—whose presence decreases the solubility of oxygen. The oxidation is said to depend on the non-ionized portion of the dissolved salt. The relative rates of oxidation of chloride, sulphate, and acetate are as 1:10:100. The marked slowness of the oxidation of acidified soln. of ferrous sulphate was emphasized by C. Baskerville and R. Stevenson, who found

that no appreciable oxidation occurred when a stream of air was bubbled for 3 hrs. through a soln. of the salt even in the presence of salts of cobalt, chromium, copper, and manganese which usually acted as carriers of oxygen. J. H. Reedy and J. S. Machin found that the reaction is positively catalyzed by manganese dioxide.

J. W. McBain, H. Vierling, E. Posnjak, J. A. N. Friend and E. G. K. Pritchett, W. A. Damon, I. K. Phelps, J. H. Reedy and J. S. Machin, P. K. Banerjee, and C. A. Peters and S. E. Moody also showed that the oxidation is a slow process, and J. W. McBain added that it increases with the conc. of the ferrous sulphate, and of oxygen, but it is not much affected by the acidity of the soln. although the presence of sulphuric acid has a retarding influence. P. K. Banerjee said that the reaction is slow, approximately unimolecular, and is hastened by the presence of potassium sulphate but retarded by other sulphates—particularly sulphuric acid and copper sulphate. E. Laska found that dil. soln. with about 0.24 per cent. of sulphuric acid resist oxidation in air between 15° and 96°. Thus, with 0.02*M*-FeSO₄, the permanganate titre was initially 5.45; after 8 days, 5.43; 71 days, 5.37; 97 days, 5.37; and 123 days, 5.36; when 0.025*M*-H₂SO₄ was also present, the initial titre was 5.5, and it remained 5.5 after 39 days. According to A. B. Lamb and L. W. Elder, the oxidation of soln. of ferrous sulphate by oxygen is greatly accelerated by increasing the rate of stirring the liquid; by increasing the conc. of the dissolved oxygen, the rate of oxidation increases in accord with the assumption that the reaction is unimolecular with respect to oxygen, as in the experiments of

FIG. 646.—The Effect of the Acidity of the Solution on the Rate of Oxidation of Ferrous Sulphate.

J. W. McBain, and G. Just; and by increasing the conc. of the ferrous sulphate, the rate of oxidation increases in accord with the assumption that the reaction is bimolecular with respect to the ferrous salt as in the experiments of J. W. McBain, F. R. Ennos, and J. Boselli. The effect of varying the concentration of the sulphuric acid in the soln. is indicated by the curve, Fig. 646. J. Cornog and A. Herschberger found that there is but little oxidation when $p_H < 5$; and with soln. buffered to $p_H = 5$, the degree of oxidation increased with increasing ion concentration, but at $p_H = 10$, it decreased with an increasing concentration of the iron. The percentage x of iron oxidized by aeration of the soln. of $p_H = 5$ in t hrs. is: $t = 0.032x - 0.01$. The subject was studied by R. S. Martin, H. O. Halvorsen and R. L. Starkey, and L. Michaelis and C. V. Smythe; and the anodic oxidation, by A. Pletenew and W. N. Rosow.

The rate of oxidation is accelerated in the presence of salts of palladium, platinum, copper, and gold. E. Jordis and H. Vierling, and T. Warynsky also found that the oxidation of the soln. of ferrous salts is favoured by platinum salts. E. Laska, however, observed that the rate of oxidation is very little influenced by the presence of uranyl, vanadium, silver, zirconium, nickel, cerium, beryllium, stannous, and cobaltous salts, of ammonium chloride, or of arsenic trioxide. The activity of the catalysts increases more or less regularly with their concentration. The results are modified by variations of temp., such that there are certain limits within which the catalyst becomes more active with a rise of temp. Thus, with 0.02*M*-FeSO₄, and 0.5*M*-CuCl₂, the fall in the permanganate titre in 12 days, was:

96°	80°	60°	40°	15° (47 hrs.)
5.25→4.10	5.42→3.50	5.45→3.65	5.70→4.45	5.57→4.50

So that with this particular catalyst the activity increases with a rise of temp. from 15° to 80°, and then begins to decrease. E. M. Michelson, and J. W. McBain found that the rate of oxidation of 0.1*N*-FeSO₄ with *N*-H₂SO₄ is increased 3- to 4-fold by a rise of temp. of 15°. E. Laska also found that the H⁺-ion concentration has

no influence, since he found that with different proportions of sulphuric acid, the permanganate titre of the 0.02M-FeSO₄ after 123 days changed from the initial value 5.43 :

H ₂ SO ₄	.	.	0	2M-	M-	0.5M-	0.05M-
Titre	.	.	5.37	5.42	5.39	5.41	5.40

and with boric acid in 0.02M-FeSO₄ with 0.025M-H₂SO₄ :

H ₃ BO ₃	.	.	0	0.25N-	0.125N-	0.0625N-
Titre	.	.	5.37	5.31	5.30	5.29

This is not in accord with the results of other observers. In the presence of hydrochloric acid, with 0.02M-FeSO₄, the titre fell in 123 days, from 5.43 :

HCl	.	.	0	2N-	N-	0.5N-	0.05N-
Titre	.	.	5.37	4.70	5.30	5.34	5.42

so that hydrochloric acid favours the oxidation of the soln. This is attributed to the formation of some ferrous chloride : $\text{FeSO}_4 + 2\text{HCl} \rightleftharpoons \text{H}_2\text{SO}_4 + \text{FeCl}_2$, which is rather susceptible to atm. oxidation. Nitric acid in traces, has very little action, but with higher concentrations, it favours oxidation. Thus, with 0.02M-FeSO₄ with an initial titre of 5.43, in the presence of nitric acid, the titre fell to :

HNO ₃	.	.	0	0.05N-	0.5N-	N-	2N-
Titre	.	.	5.37	5.15	0	0	0

A. B. Lamb and L. W. Elder observed that neutral salts—potassium, sodium, magnesium, zinc, manganous, nickel, and chromic sulphates, and sodium acetate or normal phosphate—have no appreciable effect on the oxidation of ferrous sulphate. The effects with copper sulphate are summarized in Figs. 647 and 648,

FIG. 647.—The Effect of Copper Sulphate.

FIG. 648.—The Effect of Acid and Copper Sulphate.

and the curves indicate that the acceleration produced by copper sulphate increases with its concentration, and with the acidity of the soln. This confirms the observations of J. Boselli, and J. Cornog and A. Herschberger, contrasted with those of P. K. Banerjee. The rate of oxidation with 0.023M-sodium pyrosulphate is quickened about 1000 times, and this the more, as shown by J. H. C. Smith and H. A. Spoehr, the faster is the rate of stirring. The presence of steam-activated, coco-nut charcoal, or of platinum black hastens the reaction; the accelerating effect with silica gel is small. The reaction is retarded by phenyl urea, amyl alcohol, and acetanilide.

E. Posnjak's observations on the oxidation of ferrous sulphate soln. in the presence of copper sulphate, as catalyst, do not agree with those of E. Laska. The copper sulphate accelerates the rate of oxidation to a marked degree. The results with 0.1N- and 0.5N-FeSO₄, with and without 0.0036M-CuSO₄, are shown in Fig. 649. The oxidation follows the rule for bimolecular reactions, $k = x/ta(a-x)$, where k , without catalyst, is 0.00016, and 0.0035 for 0.1N-FeSO₄ with 0.0036M-CuSO₄, and 0.00052 for 0.5N-FeSO₄ with 0.0036M-CuSO₄. The acceleration due to the presence of copper sulphate is explained by E. Posnjak on the assumption that a state of equilibrium is set up in the soln. $2\text{FeSO}_4 + 2\text{CuSO}_4$

$\rightleftharpoons \text{Fe}_2(\text{SO}_4)_3 + \text{Cu}_2\text{SO}_4$, or $\text{Fe}^{++} + \text{Cu}^{+} \rightleftharpoons \text{Fe}^{+++} + \text{Cu}^{\cdot}$. This is supported by the observations of H. C. Biddle, L. Maquenne and E. Demousay, F. Herrmann, E. Müller and F. Kapeller, J. A. Verhoeff, P. K. Banerjee, H. R. Ellis and W. H. Collier, and C. van Brunt. E. Posnjak said that the cuprous salt is readily oxidized, and that the acceleration produced by cupric sulphate is due to the oscillation of some of the copper between two stages of oxidation, which, combined with the equilibrium existing between ferrous and cupric ions, is probably responsible for the rapid formation of the ferric salt in soln. The effectiveness of the cupric sulphate decreases with increasing conc. of ferric ions in accord with the theory. A. B. Lamb and L. W. Elder found that those substances which, according

FIG. 649.—The Rate of Oxidation of Solutions of Ferrous Sulphate.

ing to G. Lemoine, O. Warburg, and V. L. Bohnson and A. C. Robertson, hasten the decomposition of hydrogen dioxide—*e.g.*, charcoal, platinum, and cupric salts—in the presence of ferrous salts, also accelerate the oxidation of ferrous sulphate soln. It has been suggested that the oxidation process involves the formation of hydrogen dioxide: $2\text{FeO} + \text{O}_2 + \text{H}_2\text{O} = \text{Fe}_2\text{O}_3 + \text{H}_2\text{O}_2$, by a slow primary reaction followed by the rapid reaction: $2\text{FeO} + \text{H}_2\text{O}_2 = \text{Fe}_2\text{O}_3 + \text{H}_2\text{O}$, but A. K. Goard and E. K. Rideal observed that copper salts do not catalyze the oxidation of ferrous salts by hydrogen dioxide in acidic soln. It is very unlikely that hydrogen dioxide is formed by the action of oxygen on water since the equilibrium partial press. of hydrogen dioxide in a 1 : 1 gaseous mixture of oxygen and air is of the order of 10^{-22} atm. Hence it is doubtful if hydrogen dioxide is the effective agent in these oxidations. It is more likely that the catalysis is due to the formation of specific peroxides, minute quantities of such a substance have been extracted from aerated charcoal by means of sulphuric acid.

R. Thomas and E. T. Williams, and N. McCulloch also observed that the presence of nitric oxide favours the oxidation of ferrous sulphate soln. According to W. S. Hendrixson, when ferrous iron is added to a dil. soln. of an oxidizing agent in sulphuric acid, there is a rise in the potential of electrodes by accelerating the rate at which they take up their full charges. In all but extremely dil. soln., the electrodes reach saturation after several hours, and normal falls of potential are then produced by the addition of ferrous sulphate. For the basic salt **ferrous oxysulphate**, $\text{FeO} \cdot \text{FeSO}_4$, *vide supra*, the electrolysis of soln. of ferrous sulphate. W. Feitknecht found that the space-lattice of $\text{FeSO}_4 \cdot 3\text{Fe}(\text{OH})_2$ corresponds with alternate layers of hydroxide and of the normal salt.

In alkaline soln., E. Müller and F. Kapeller found that the oxidation is fairly rapid. The oxidation of certain soln. of ferrous salts may be accelerated by certain micro-organisms called iron bacteria, examples of whose action in the production of natural deposits of bog-iron ore were discussed in connection with limonite. E. M. Mumford, indeed, showed that bacteria were able completely to oxidize a dil. soln. of ammonium ferrous sulphate into hydrated ferric oxide in 36 hrs. at 37° .

The general results show that to prevent the oxidation of soln. of ferrous sulphate the soln. can be made up with well-boiled water, and kept in an atmosphere of an inert gas—hydrogen (N. A. Tananaeff), nitrogen (J. A. Hedvall and J. Heuberger), or carbon dioxide (G. Bailhache). Contact of the soln. with iron (O. Mustad) is not satisfactory. A layer of an inert liquid like benzene (F. W. Horst) over the soln. is moderately successful for a few days. F. K. Cameron observed that at higher temp., an atmosphere of water vapour will prevent access of oxygen enabling the soln. to be kept for some weeks, and at a lower temp. a few per cent. of alcohol has proved effective.

The solubility of ferrous sulphate in **water**, and the conditions of equilibrium of the various hydrates, have been discussed previously; the hydrolysis of the salt in aq. soln. has also been described. A. K. Bhattacharya and N. R. Dhar found that with a sulphuric acid soln. in light of wave-length 8500 Å.:

		30°	35°	40°
Velocity coeff.	{ in dark	0.00377	0.000675	0.00112
	{ in light	0.00903	0.00153	0.00246
Quantum efficiency for 8500 Å. . .		5.4	8.9	13.4

The temp. coeff. of the reactions are less in light than in darkness. P. Rohland observed that "burnt" and powdered ferrous sulphate "sets" when mixed with water almost as if the salt were plaster of Paris. A. Krause studied the hydrolysis of ferrous sulphate and found that the H⁺-ion conc. is $p_H=3.5$, whereas that for ferric sulphate is $p_H=1.3$ in agreement with the fact that ferrous hydroxide is a stronger base than ferric hydroxide. The iso-electric point for ferrous hydroxide soln. is $p_H=11.5$, and for ferric hydroxide $p_H=7.7$. According to C. Weltzien, **hydrogen dioxide** precipitates $2Fe_2O_3 \cdot SO_3 \cdot 8H_2O$ from aq. soln. of ferrous sulphate: $6FeSO_4 + 3H_2O_2 = 2Fe_2O_3 \cdot SO_3 + 3H_2O + Fe_2O_3 \cdot 5SO_3$. C. F. Schönbein showed that in many reactions, iron salts can act as carriers of oxygen, and H. J. H. Fenton explained the oxidation of tartaric acid to dihydroxymaleic acid in the presence of, say, ferrous sulphate, by assuming that bivalent iron replaces the two non-hydroxylic hydrogen atoms. The ferrous iron of the intermediate compound is then oxidized, and the tervalent iron breaks away leaving dihydroxymaleic acid:

The reaction was studied by A. T. Küchlin, F. Haber and J. Weiss, D. R. Hale, and W. Manchot. W. Manchot and co-workers, and J. Brode suggested that in the case of hydrogen dioxide, the iron is converted into an unstable, complex higher oxide, Fe_2O_5 , or $Fe_2O_3 \cdot 2H_2O_2$ —the primary oxide of W. Manchot—which is then reduced by the oxidizable substance. C. S. Mummery supposed that the ferrous sulphate unites with the hydrogen dioxide to form what he called a perhydrol, $HSO_4.Fe.O.OH$. It is supposed that the monohydrated ferrous sulphate has the constitution: $HSO_4.Fe.OH$, which then reacts with hydrogen dioxide: $HSO_4.Fe.OH + H_2O.OH \rightleftharpoons HSO_4.Fe.O.OH + H_2O$. This imaginary product is supposed to be analogous with monopersulphuric acid, $HO.SO_2.O.OH$, and, in consequence, the product is assumed to be a powerful oxidizer. The hypothetical perhydrol is assumed to be alternately formed and decomposed in a never-ending cycle so long as the oxidizable substance and hydrogen dioxide are present. D. R. Hale, R. Kuhn and A. Wassermann, S. Goldschmidt and co-workers, and E. Spitalsky and N. Petin studied the reaction between hydrogen dioxide, ferrous sulphate, and potassium iodide—*vide* ferric sulphate and hydrogen dioxide. The activity of ferrous sulphate was found by A. M. Malkoff and N. Zvetkova to be retarded by phosphate. N. N. Biswas and N. R. Dhar studied the chemiluminescence of organic substances in the presence of ferrous sulphate and hydrogen dioxide. H. Kwasnik found that an aq. soln. of ferrous sulphate reacts with **barium dioxide** giving off oxygen and forming hydrated ferric oxide; but H. Frischer said that **sodium dioxide** and barium dioxide under these conditions give off no oxygen and precipitate basic ferric sulphate, $Fe_2(OH)_4SO_4$.

According to K. H. Butler and D. McIntosh, heptahydrated ferrous sulphate is insoluble in liquid **chlorine**. Aq. soln. of the salt are oxidized by the halogens; thus, when gaseous chlorine acts on the soln., ferric sulphate and chloride are produced and the thermal value of the reaction is 24.436 Cals. per mol. of $FeSO_4$. The reaction with chlorine and **bromine** was discussed by M. C. Schuyten; A. W. Francis studied the speed of the reaction with bromine. M. C. Schuyten investigated the action of **iodine**; A. Berthoud and S. von Allmen, R. C. Banerji and N. R. Dhar, B. K. Mukerji and N. R. Dhar, A. K. Bhattacharya and N. R. Dhar, and N. R. Dhar,

the photochemical oxidation of a soln. of ferrous sulphate by iodine; and D. R. Hale studied the induced reaction between ferrous sulphate, potassium iodide, and hydrogen dioxide. The use of iron salts as halogen carriers in organic chemistry was discussed by B. Aronheim, L. Meyer, L. Meyer and A. Scheufelen, A. G. Page, A. Scheufelen, and C. Willgerodt. G. B. Heisig, and A. C. Christomanos found that a soln. of ferrous sulphate is oxidized to a ferrous salt by **iodine trichloride**. R. Kane said that anhydrous ferrous sulphate is indifferent towards gaseous **hydrogen chloride**, but at an elevated temp., when the thermal decomposition of the sulphate is proceeding, C. Hensgen observed that ferric chloride is formed. F. Ephraim observed that no complex is formed with hydrogen chloride. G. Gore found that in liquefied hydrogen chloride the heptahydrate becomes yellowish-white and opaque, without dissolving. R. Kane said that the salt is soluble in hot **hydrochloric acid**. A. L. Young and G. F. Dixon found that when a gram of the heptahydrate mixed with 3.5 c.c. of hydrochloric acid, of sp. gr. 1.153, is evaporated on a water-bath, 2.3 per cent. of the iron is converted into chloride. C. Hensgen observed that when a conc. soln. of ferrous sulphate is saturated with hydrogen chloride, pale green needles of $\text{FeCl}_3 \cdot \text{H}_2\text{O}$, and tabular plates of $\text{FeSO}_4 \cdot 6\text{H}_2\text{O}$ separate from the soln. A. J. Balard found that ferrous sulphate is oxidized to ferric sulphate by **hypochlorous acid** and **hypochlorites**: $2\text{Fe}^{++} + \text{H}^+ + \text{HOCl} = 2\text{Fe}^{+++} + \text{Cl}^- + \text{H}_2\text{O}$. The reaction was discussed by J. Dalton, C. R. A. Wright, T. Wittstein, E. Biltz, and N. Graeger. Ferrous sulphate reacts instantly with **chlorine dioxide**; K. von Garzarolli-Thurnlackh and K. von Hayn represent the reaction: $\text{ClO}_2 + 5\text{Fe}^{++} + 4\text{H}^+ = \text{Cl}^- + 5\text{Fe}^{+++} + 2\text{H}_2\text{O}$; and E. Lenssen added that if an aq. soln. of chlorine dioxide be added to a dil. acidic soln. of a ferrous salt, an amethyst colour first appears, and this changes to yellow after a few seconds. W. Oechsli represented the reaction with **barium chlorite**: $\text{Ba}(\text{ClO}_2)_2 + 8\text{FeSO}_4 + 5\text{H}_2\text{SO}_4 = 4\text{Fe}_2(\text{SO}_4)_3 + 2\text{HCl} + \text{BaSO}_4 + 4\text{H}_2\text{O}$; the ferrous sulphate was found by A. Schleicher and W. Wesly not to be oxidized in neutral soln. C. R. A. Wright showed that ferrous sulphate in acidic soln. is oxidized by **chloric acid**, and that the speed of the reaction is dependent on the temp., and on the conc. of the acid in the soln.; and A. Carnot, and M. Herschkowitsch said that the reaction is quantitative; but with aluminium chlorate, D. K. Dobrosserdoff found that the reduction is only partial. J. J. Hood found that the speed of the reaction is retarded by sodium, potassium, ammonium, lithium, magnesium, zinc, and cadmium sulphates, by potassium and ammonium chlorides, and by potash-alum, and ammonium-alum; sodium chloride has very little effect; whilst magnesium, zinc, and cadmium chlorides accelerate the reaction; T. F. Rutter showed that the reaction is also accelerated by vanadium salts. W. F. Green said that the reaction is not affected by the presence of ferric salts. R. R. Enfield studied the accelerating influence of acids; J. J. Hood represented the reaction in the presence of an excess of acid by $6\text{Fe}^{++} + \text{ClO}_3^- + 6\text{H}^+ = 6\text{Fe}^{+++} + \text{Cl}^- + 3\text{H}_2\text{O}$, and said that the reaction is of the second order with the velocity proportional to the product of the concentrations of the two salts, the acid exerting an accelerative influence, the velocity increasing rather more rapidly than the acid concentration, but A. A. Noyes and R. S. Wason represented it as a reaction of the third order; the reaction appears of the second order only when an excess of acid is present. The reaction was studied by F. H. MacDougall, C. F. Schönbein, D. Vitali, F. Becker, C. O. Harvey, W. Bray, and W. F. Green. F. Bellamy observed that in consequence of the acid nature of anhydrous ferrous sulphate, its presence accelerates the thermal decomposition of **potassium chlorate**, with the formation of chlorine; and M. Herschkowitsch added that a well-dried mixture of the two salts does not react at 100° ; but if the mixture be moistened with a few drops of water, or if commercial sulphate or the heptahydrate be used, chlorine, hydrogen chloride, and chlorine dioxide are evolved, and ferric sulphate and chloride remain. L. C. A. Barreswil observed that a soln. of potassium chlorate and ferrous sulphate in the cold gives a red precipitate of a hydrated basic ferric salt, whilst a hot soln. yields a yellow,

anhydrous precipitate sparingly soluble in acids. A mixture of hydrochloric acid and potassium chlorate oxidizes ferrous sulphate to a ferric salt. The reduction of chlorates in alkaline soln. by ferrous sulphate was found by C. Stelling to be quantitative. Observations were made by F. Becker, I. Bhaduri, N. R. Dhar, M. Couleru, C. O. Harvey, I. K. Phelps, C. Russo and G. Sensi, and E. C. Wagner. Soluble iodides reduce chlorates to chlorides: $\text{KClO}_3 + 6\text{KI} + 3\text{H}_2\text{SO}_4 = \text{KCl} + 3\text{K}_2\text{SO}_4 + 3\text{I}_2 + 3\text{H}_2\text{O}$; the reaction is greatly accelerated by the presence of ferrous or ferric salts; and, according to W. D. Bonner and H. Romeyn, the reaction $\text{Fe}^{++} + \frac{1}{2}\text{I}_2\text{Aq.} = \text{Fe}^{+++} + \text{I}^-$ goes to an end in the presence of a phosphate and a moderate concentration of acid. In the former case, W. F. Green, and L. Pisarschewsky and N. Averkéeff assumed that the iodine forms ferrous iodide which is then oxidized to the ferric salt, and that the catalytic effect is due to the cyclic formation and decomposition of ferric iodide: $\text{KClO}_3 + 6\text{FeI}_2 + 6\text{KI} + 3\text{H}_2\text{SO}_4 = \text{KCl} + 3\text{K}_2\text{SO}_4 + 6\text{FeI}_3 + 3\text{H}_2\text{O}$, and $2\text{FeI}_3 = 2\text{FeI}_2 + \text{I}_2$. C. Löwig observed that **potassium bromate** reacts with a soln. of ferrous sulphate forming a brownish-red precipitate which is probably ferrous bromate. According to S. E. Moody, hydrolysis occurs when a soln. of ferrous sulphate is boiled with **potassium iodate** and iodide: $3\text{FeSO}_4 + 5\text{KI} + \text{KIO}_3 + 3\text{H}_2\text{O} = 3\text{Fe}(\text{OH})_2 + 3\text{K}_2\text{SO}_4 + 3\text{I}_2$; and the excess of iodate then oxidizes the hydrated ferrous to ferric oxide: $6\text{Fe}(\text{OH})_2 + \text{KIO}_3 + 3\text{H}_2\text{O} = \text{KI} + 6\text{Fe}(\text{OH})_3$. The subject was studied by G. B. Heisig.

The reaction between **sulphur** and ferrous sulphate: $\text{FeSO}_4 + 2\text{S} = \text{FeS} + 2\text{SO}_2$, studied by F. Stolba, H. Schiff, E. Glatzel, and H. Rose, has been discussed in connection with the preparation of ferrous sulphide and iron disulphide; K. Brückner noted that some iron disulphide is formed. G. Vortmann and C. Padberg observed no chemical change occurs when a soln. of ferrous sulphate is boiled with sulphur. The action of **hydrogen sulphide** has been discussed in connection with the preparation of ferrous sulphide and of iron disulphide. The action of **ammonium and alkali sulphides** has been indicated in connection with the reactions of analytical interest. The aq. soln. was found by E. Schürmann to be completely decomposed by **manganese sulphide**, and partially decomposed by **thallous, cobalt, and nickel sulphides**, and only a little decomposed by zinc sulphide. The reaction with eq. quantities of cobalt, or nickel, sulphide, with ferrous sulphide results in the formation of a complex sulphide; and F. Feigl said that when the ratio of cobalt or nickel sulphide to the iron in the ferrous sulphide is as 2 : 1, approximately 30 per cent. of the iron in the salt is transformed. J. d'Ans, and G. Keppeler and J. d'Ans observed that the anhydrous sulphate above 600° decomposes in a current of **sulphur dioxide**, and that the result is the same as if the sulphate had been heated in an indifferent gas; no ferrous oxide is formed; the products of the reaction are ferric oxide, and sulphur dioxide and trioxide. L. Meyer found that ferrous sulphate comes after manganous and copper salts in the order of activity as a catalyst in the oxidation of sulphur dioxide. K. F. Ochs studied the subject. C. F. Schönbein observed that if the crystals of the heptahydrate are quite free from ferric sulphate they remain colourless when treated with sulphurous acid, but if a trace of ferric sulphate be present, the colour changes to yellowish-brown.

According to A. Bussy and L. R. Lecanu, anhydrous or heptahydrated ferrous sulphate is soluble in conc. **sulphuric acid**, of sp. gr. 1.843, forming a rose- or purple-coloured liquid; and E. Divers and T. Shimidzu, G. Fownes, W. B. Giles, and T. Scheerer found that when the heptahydrate is boiled with conc. sulphuric acid, sulphur dioxide is evolved: $2\text{FeSO}_4 + 2\text{SO}_3 = \text{Fe}_2(\text{SO}_4)_3 + \text{SO}_2$. J. Kendall and A. W. Davidson observed that mixtures of 0.22, 0.31, 0.40, 0.51, and 0.63 per cent. of anhydrous ferrous sulphate and sulphuric acid had the respective f.p. 30.2° , 42.3° , 48.6° , 57.7° and 63.8° . The upward slope of the curve indicates that an acid salt is present. The f.p. of higher concentrations were not measured because the mixtures became cloudy owing to the oxidation of the ferrous sulphate, by the sulphuric acid, to the less soluble ferric sulphate. The effect of sulphuric acid in retarding the aerial oxidation of a soln. of ferrous sulphate has been previously

V. Komar reported crystals of normal **ferrous hydrosulphate**, $\text{FeO} \cdot 2\text{SO}_3 \cdot \text{H}_2\text{O}$, or $\text{FeSO}_4 \cdot \text{H}_2\text{SO}_4$, or $\text{Fe}(\text{HSO}_4)_2$, to be formed by the evaporation of a soln. of ferrous sulphate with sulphuric acid of sp. gr. 1.3 to 1.4. F. B. Kenrick observed it to be the solid phase in the ternary system $\text{FeSO}_4\text{--H}_2\text{SO}_4\text{--H}_2\text{O}$ at 25° with soln. containing SO_3 : $1.342\text{H}_2\text{O}$ to $1.595\text{H}_2\text{O}$. The prismatic crystals are well-formed, and, under the microscope, resemble those of $\text{Na}_2\text{SO}_4 \cdot 10\text{H}_2\text{O}$. It is thought that this salt may be identical with the *ferrous pyrosulphate*, FeS_5O_2 , reported by T. Bolas to be formed by cooling a mixture of 9 vols. of conc. sulphuric acid with 1 vol. of a sat. soln. of ferrous sulphate. F. B. Kenrick obtained small, colourless, hexagonal crystals of **ferrous hydrosulphatosulphate**, $2\text{FeO} \cdot 3\text{SO}_3 \cdot 2\text{H}_2\text{O}$, or $2\text{FeSO}_4 \cdot \text{H}_2\text{SO}_4 \cdot \text{H}_2\text{O}$, or $\text{FeSO}_4 \cdot \text{Fe}(\text{HSO}_4)_2 \cdot \text{H}_2\text{O}$, from soln. containing between SO_3 : $1.637\text{H}_2\text{O}$ to SO_3 : $2.186\text{H}_2\text{O}$. It is thought that the crystals may be the same as those reported by F. Jeremin to contain $\text{FeSO}_4 \cdot 5\text{H}_2\text{SO}_4 \cdot 5\text{H}_2\text{O}$, or $\text{FeO} \cdot 6\text{SO}_3 \cdot 10\text{H}_2\text{O}$, *i.e.* **ferrous pentahydrosulphatosulphate**; F. Jeremin prepared this salt, in unstable, greenish crystals, by rapidly mixing a sat. soln. of ferrous sulphate with at least 4 vols. of sulphuric acid of sp. gr. 1.83. P. A. von Bonsdorff obtained colourless plates, sparingly soluble in water, and of the composition **ferrous trihydrosulphatosulphate**, $\text{FeO} \cdot 4\text{SO}_3 \cdot 3\text{H}_2\text{O}$, or $\text{FeSO}_4 \cdot 3\text{H}_2\text{SO}_4$, by mixing conc. soln. of ferrous sulphate and sulphuric acid until the sp. gr. is 1.33; evaporating the liquid over conc. sulphuric acid until its sp. gr. is 1.50; and crystallizing. F. B. Kenrick said that the salt is stable in soln. with between SO_3 : $1.22\text{H}_2\text{O}$ to SO_3 : $1.342\text{H}_2\text{O}$.

M. Berthelot observed that when **persulphuric acid** is dropped into an acidic soln. of ferrous sulphate, an unstable brown product is formed which with further additions of acid is decomposed to form a colourless soln. R. N. J. Saal, and T. S. Price studied the catalytic action of ferrous salts on the reaction between **persulphates** and iodides: $\text{K}_2\text{S}_2\text{O}_8 + 2\text{KI} = 2\text{K}_2\text{SO}_4 + \text{I}_2$. According to G. Lunge, sulphuric acid containing **selenium dioxide** gives a brownish-yellow, or yellowish-red ring when dropped into a soln. of ferrous sulphate, the colour does not vanish when the liquid is warmed as is the case with the brown ring formed by nitric oxide. E. Keller observed that a soln. of selenium dioxide in hydrochloric acid, exceeding 30 per cent. HCl, deposits all the selenium in 24 hrs., but **tellurium dioxide** under similar conditions does not react with the hydrochloric acid. F. D. Crane observed that the precipitation of tellurium with ferrous sulphate soln. occurs only when the soln. of tellurium tetrachloride is free from the dichloride.

E. C. Franklin and C. A. Kraus observed that ferrous sulphate is insoluble in liquid **ammonia**. According to F. Ephraim, when ammonia is passed over anhydrous ferrous sulphate, heat is evolved and the salt swells up forming a voluminous, white powder whose composition is not far from $\text{FeSO}_4 \cdot 6\text{NH}_3$; if the temp. be raised high enough, W. R. Hodgkinson and C. C. Trench observed that the anhydrous or hydrated sulphate is reduced to iron containing 1 to 2 per cent. of sulphur. The action of ammonia on hydrated ferrous sulphate or on aq. soln. furnishes a series of amines. A. Kaufmann observed that when reduced iron is dissolved in a hot, ammoniacal, saturated soln. of ammonium sulphate, the yellow soln. probably contains ferrous aminosulphate, though none was isolated. F. Ephraim prepared **ferrous hexamminosulphate**, $\text{FeSO}_4 \cdot 6\text{NH}_3$, or $[\text{Fe}(\text{NH}_3)_3]\text{SO}_4$, by passing ammonia over anhydrous ferrous sulphate. The voluminous, white powder is readily oxidized. Its dissociation press., p mm., is:

	73°	82°	88.5°	94.5°	96°	98.5°	102.5°	107°	108°	109.5°
p . . .	150	256	350	464	500	551	642	740	760	788

The compound is stable up to 91° , beyond which it begins to form the tetrammine, Fig. 651. The heat of dissociation to the tetrammine is 13.65 Cals. per mol. of ammonia. F. Ephraim discussed the relation between the dissociation temp. and the at. vol. F. Müller gave -18° to 75° for the temp. of dissociation of the heptammine. E. Weitz and H. Müller were unable to prepare the hexammine by

wet processes; the nearest they could produce was **ferrous pentamminosulphate**, $\text{FeSO}_4 \cdot 5\text{NH}_3 \cdot \text{H}_2\text{O}$, or *ferrous aquopentamminosulphate*, $[\text{Fe}(\text{NH}_3)_5(\text{H}_2\text{O})]\text{SO}_4$, which they obtained, in green, rhombohedral crystals, by driving out the air from a soln. of 5 grms. of Mohr's salt in 200 c.c. of water, passing ammonia into the well-

FIG. 651. — The Dissociation Curve of the Ferrous Amminosulphates.

cooled liquid so that the hydroxide first precipitated is redissolved, filtering in an atm. of ammonia, and allowing the soln. to crystallize. F. Müller gave 75° to 95° for the dissociation temp. of the pentammine. J. A. Verhoeff employed an analogous process, but precipitated the salt by the addition of alcohol sat. with ammonia to the well-cooled liquid. F. Ephraim observed that when the hexammine is heated to nearly 110°, it forms **ferrous tetramminosulphate**, $\text{FeSO}_4 \cdot 4\text{NH}_3$, with a dissociation press. of 500 mm. at 117°, and 760 mm. at 125°—Fig. 651. He studied the relation between the dissociation temp. and the at. vol.; and found for the heat of dissociation to the diammine, 14.32 Cals. per mol. of ammonia. W. Peters obtained a *monohydrate*, $\text{FeSO}_4 \cdot 4\text{NH}_3 \cdot \text{H}_2\text{O}$, or $[\text{Fe}(\text{NH}_3)_4]\text{SO}_4 \cdot \text{H}_2\text{O}$, by the action of ammonia on monohydrated ferrous sulphate, at room temp. When kept in vacuo, this salt passes into the diammine. G. Spacu prepared the same salt by passing a brisk current of dry ammonia over the pyridine sulphate, $[\text{Fe}(\text{C}_5\text{H}_5\text{N})_3(\text{H}_2\text{O})]\text{SO}_4 \cdot \text{H}_2\text{O}$. It is almost insoluble in water; and is hydrolyzed in aq. soln.; it is insoluble in most solvents, but it dissolves in dil. sulphuric acid. F. Müller gave 95° to 110° for the dissociation temp. F. Ephraim found that **ferrous triamminosulphate**, $\text{FeSO}_4 \cdot 3\text{NH}_3$, is formed when the higher ammine is heated between 120° and 123°—Fig. 651—and W. Peters obtained the *monohydrate*, $\text{FeSO}_4 \cdot 3\text{NH}_3 \cdot \text{H}_2\text{O}$, by the action of ammonia on the hydrated diammine. F. Ephraim found that the triammine passes into **ferrous diamminosulphate**, $\text{FeSO}_4 \cdot 2\text{NH}_3$, when heated to 221° to 222°; and W. Peters prepared the *monohydrate*, $\text{FeSO}_4 \cdot 2\text{NH}_3 \cdot \text{H}_2\text{O}$, by keeping the hydrated tetrammine in vacuo. F. Ephraim prepared **ferrous monamminosulphate**, $\text{FeSO}_4 \cdot \text{NH}_3$, by heating a higher ammine between 300° and 400°—Fig. 651. F. Müller gave 180° to 190° for the dissociation temp. of the diammine, and 192° to 225° for that of the monammine. H. Weitz observed that no nitrosyl ammine is formed when nitric oxide is passed into an ammoniacal soln. of ferrous and ammonium sulphates. O. R. Foz and L. le Boucher studied the amminosulphates.

H. A. von Vogel found that on adding a soln. of **ammonium chloride** to one of ferrous sulphate, a complex salt is formed. A. Kurtenacker and F. Werner studied the catalytic decomposition of **hydroxylamine** by ferrous sulphate. According to T. W. B. Welsh and H. J. Broderson, ferrous sulphate is only slightly soluble in liquid **hydrazine**, gas is evolved, and a yellow precipitate is formed. The soln. is a poor conductor of electricity; and a black deposit appears on the cathode, and it is soluble in hydrochloric acid. H. Schjerring said that ferrous sulphate and **phenylhydrazine** form the complex salt. T. Curtius and J. Rissom, and L. M. Dennis and A. W. Browne noted that **sodium azide**, when shaken in air with a soln. of ferrous sulphate, develops a blood-red coloration. C. T. Dowell and W. C. Bray found that when a soln. of ferrous sulphate is treated with a soln. of **nitrogen trichloride**, NCl_3 , in carbon tetrachloride, an ammonium salt is formed, and nitrogen is evolved. According to W. Manchot and co-workers, aq. soln. with 0, 10.938, and 21.845 grms. of FeSO_4 per 100 c.c. dissolve respectively 53.3, 34.0, and 21.6 c.c. of **nitrous oxide** per 100 c.c. of soln. According to V. Thomas, unlike ferrous chloride and bromide, anhydrous ferrous sulphate absorbs no **nitric oxide**; but J. Priestley observed that a soln. of ferrous sulphate is coloured dark brown by nitric oxide, and when the sat. aq. soln. is treated with the gas, W. Manchot and co-workers—F. Huttner, H. Haunschild, and E. Linckh—observed the

formation of **ferrous nitrosylsulphate**, $\text{FeSO}_4\cdot\text{NO}$, and of **ferrous heminitrosylsulphate**, $2\text{FeSO}_4\cdot\text{NO}\cdot 13\text{H}_2\text{O}$. The reaction was studied by E. Pélégot, H. Davy, F. H. A. von Humboldt and L. N. Vauquelin, L. Cambi and A. Clerici, W. Kalle and W. Prickarts, G. von Hüfner, L. Carius, V. A. Jacquelain, A. Bussy and L. R. Lecanu, E. Desbassyns de Richemont, J. Gay, F. Raschig, F. L. Usher, E. Lenssen, etc.—*vide* 8, 49, 35. J. Bystron and K. von Vietinghoff observed that when **nitrogen peroxide** is passed into a soln. of ferrous sulphate, a basic ferric salt is precipitated. A. Thum found that a soln. of **alkali hyponitrite** reacts with a freshly-prepared soln. of ferrous sulphate forming a light green precipitate which soon becomes darker, while the soln. becomes strongly acidic. Ferrous salts reduce **nitrites** to nitric oxide, owing, said P. Piccini and F. M. Zuco, to the formation of an unstable ferrous nitrite: $6\text{Fe}(\text{NO}_2)_2 = 10\text{NO} + \text{Fe}_2\text{O}_3 + 2\text{Fe}_2\text{O}_3\cdot\text{N}_2\text{O}_5$. A. Thiele said that the reaction with a conc. soln. of sodium nitrite and a hydrochloric acid soln. of ferrous sulphate can be used for making nitric oxide of a high degree of purity. When **nitric acid** is added to a soln. of ferrous sulphate, acidified with sulphuric acid, nitric oxide is formed: $6\text{FeSO}_4 + 3\text{H}_2\text{SO}_4 + 2\text{HNO}_3 = 3\text{Fe}_2(\text{SO}_4)_3 + 4\text{H}_2\text{O} + 2\text{NO}$. The latter produces a brown coloration which is applied in the so-called *ring-test* for nitric acid and the nitrates, where a cold soln. of ferrous sulphate is poured down the sides of a test-tube containing a layer of conc. sulphuric acid and the suspected nitrate. If a nitrate is present, the colour of the ring at the junction of the two liquids will be ruddy if the nitrosyl compound is formed in the conc. acid layer, and brown, if formed in the aq. soln. The coloration was also applied by L. Maugé, F. C. Bowman and W. W. Scott, and I. Bellucci to the volumetric determination of nitric acid. The brown colour is formed only in the presence of an excess of ferrous sulphate, and when nitric acid is added, the remaining ferrous sulphate is oxidized completely, and the colour then disappears. The production of the brown coloration was utilized, by L. Blum, to detect the presence of ferrous salts in the presence of the salts of some other metals. As shown by N. A. E. Millon, and V. H. Veley, ferrous sulphate retards the action of nitric acid on metals, and this is attributed by P. C. Ray to the destruction of nitrous acid during the catalytic or cyclic oxidation and reduction of the iron salt.

C. H. Knoop found that when heptahydrated ferrous sulphate is mixed with powdered phosphorite, and heated to 250° , the phosphate becomes soluble in a soln. of citric acid. T. Salzer observed that **hypophosphoric acid** or **sodium hypophosphate** produces a white precipitate with a soln. of ferrous sulphate. R. Meissner found that when **arsine** is passed into a soln. of ferrous sulphate, only 1 to 3 per cent. is absorbed. D. R. Hale studied the induced reaction with ferrous sulphate, potassium permanganate, and **sodium arsenite**. E. Schürmann observed that **arsenic sulphide** reacts partially with ferrous sulphate in aq. soln.

P. Berthier said that when ferrous sulphate is heated with **carbon** in a carbon crucible, ferrous sulphide is formed; and J. L. Gay Lussac observed that when the mixture is heated in a retort, sulphur and carbon dioxides are evolved, and ferric oxide free from sulphide is formed; at a higher temp., the oxide is reduced to metal: A. G. Doroschewsky and A. J. Bardt observed that ferrous sulphate intensifies the catalytic action of carbon in the oxidation of alcohols. N. Schiloff and L. Lepin studied the adsorption of ferrous sulphate from a 0.05*N*-soln. by carbon. W. A. Jakowenko found that the heptahydrate reacts with **calcium carbide** giving off the equivalent of 5.9 mol. of water in the form of acetylene. According to W. Manchot and co-workers, soln. with 0, 10.938, and 21.845 grms. of FeSO_4 per 100 c.c., dissolve 95.7, 61.6, and 41.1 c.c. of **acetylene** at 25° . C. Doelter observed that when the heptahydrate is heated in coal-gas, it is reduced to ferrous sulphide. The salts of iron are reduced to metal when heated in **carbon monoxide**, and G. P. Schweder found that when ferrous sulphate is heated in an atm. of carbon monoxide, a mixture of ferrous sulphide with iron or ferric oxide is formed. J. H. Weibel studied the action of the gas under press. on the aq. soln. E. H. Büchner, and G. Gore found that the heptahydrate is not dis-

solved by liquid **carbon dioxide**, but the salt is transformed into a white powder. A. Conduché observed that when ferrous sulphate is heated in **chloroform** vapour, it produces a mixture of ferrous and ferric chlorides from which the latter sublimes. E. Alberts similarly investigated the action of the vapour of **carbon tetrachloride**. J. Barlot and E. Chauvenet found that the anhydrous sulphate reacts with **carbonyl chloride** at 300° to 500° forming ferrous chloride, sulphuryl chloride, and carbon dioxide. According to A. W. Davidson, when ferrous sulphate is mixed with 100 per cent. sulphuric acid, and **potassium ferricyanide**, the brown colour disappears without showing any other evidence of a reaction; when the mixture is diluted with water, a blue precipitate is formed. Ferrous sulphate in alkaline soln. reduces potassium ferricyanide to the ferrocyanide on exposure to light. G. A. Barbieri studied the action of ferrous sulphate on **silver ferricyanide**. C. A. L. de Bruyn observed that absolute **methyl alcohol** dissolves the heptahydrate, and that the soln. is unstable; when a few drops of water are added, or when the soln. is warmed, the heptahydrate separates out again. P. Rohland noted that the methyl alcohol soln. reduces cupric to cuprous salts; and G. C. Gibson and co-workers obtained the complex: $2\text{FeSO}_4 \cdot 3\text{CH}_3\text{OH}$. E. F. Anthon said that ferrous sulphate is insoluble in **ethyl alcohol** of a sp. gr. less than 0.905; and that alcohol, and sulphuric acid precipitate the salt from its aq. soln. H. Schiff found that 100 parts of a sat. soln. of ferrous sulphate in 40 per cent. alcohol, at 15°, contain 0.3 per cent. of the heptahydrate. Methyl, ethyl, **propyl**, *n*- and *iso*-**butyl**, and *iso*-**amyl alcohols** are oxidized by permanganate or hydrogen dioxide in the presence of ferrous salts. A dil. soln. of ethyl alcohol, for instance, in the presence of ferrous sulphate, is oxidized to aldehyde, and in the presence of ferrous oxalate, to acetic acid; and A. G. Doroschewsky and A. J. Bardt showed that ferric salts do not act as catalytic agents in the same way. E. G. Thorin observed that the solubility of **ether** in 0.5*N*- FeSO_4 is less than in water. W. F. O. de Coninck reported the solubility of ferrous sulphate in **glycol** to be 6 per cent. G. Fuseya and K. Murata found that a mol. of ferrous sulphate unites with 6 mols. of **glycocoll** in aq. soln. J. F. Persoz found that glacial **acetic acid** precipitates ferrous sulphate completely from its aq. soln., and A. W. Davidson also added that the heptahydrate is insoluble in glacial acetic acid. W. Franke observed the formation of complex acetates. W. H. Krug and K. P. McElroy, A. Naumann, and W. Eidmann found that ferrous sulphate is insoluble in **acetone**; and A. Naumann, that it is insoluble in dry **methyl acetate**, or in **ethyl acetate**, dry or sat. with water. S. Hakomori studied the action of citric acid and of oxalic acid on ferrous sulphate; and F. Krauss and K. Berge, the effect of iron salts on the photochemical decomposition of oxalic acid. S. Goldschmidt and co-workers studied the oxidation of **glycollic acid** by hydrogen dioxide. E. Darmois observed that a soln. of ferrous sulphate enhances the dextrorotatory power of **tartaric acid**; and J. H. Long studied the inversion of **cane-sugar** by ferrous sulphate. F. Calzolari found that **hexamethylene tetramine** forms a complex: $\text{FeSO}_4 \cdot \text{C}_6\text{H}_{12}\text{N}_4 \cdot 9\text{H}_2\text{O}$; B. Emmert and H. G. Sottschneider, with **benzoylacetone**; and G. Spacu, with **aniline**, the complex: $\text{FeSO}_4 \cdot 2\text{C}_6\text{H}_5\text{NH}_2$. A. Naumann said that ferrous sulphate is insoluble in **pyridine**, but various complex salts have been obtained by W. Lang, F. Reitzenstein, G. Spacu, and R. Weinland and co-workers. F. L. Hahn and co-workers observed that ferrous sulphate forms a complex with **α -acetaminopyridine**; but E. Borsbach, and F. Blau observed no complex is formed with **quinoline**. F. Blau, H. Freundlich and V. Birstein, L. A. Welo, S. Berkman and H. Zocher, W. Biltz, and W. Manchot observed that a complex is formed with **$\alpha\alpha'$ -dipyridyl**, but H. Blau obtained no complex with the other dipyridyls— **$\alpha\beta'$** , **$\beta\beta'$** , or **$\gamma\gamma'$** —F. Blau obtained complexes with **$\alpha\alpha'$ -dipiperidyl**, and **α -phenantholine**, but not with **toluidine**, **naphthylamine**, **phenyldiamine**, or **benzidine**. G. Canneri obtained a complex with **guanidine**; P. C. and N. Ray studied the complex salts formed with **trimethylsulphonium sulphate**, and **triethylsulphonium sulphate**. D. Porret studied the oxidation of ferrous sulphate by **benzoquinone**;

F. M. Jäger and J. A. van Dijk, the complexes with **dipyridyl**. A. M. Malkoff and N. Zvetkova observed that the catalytic activity of ferrous sulphate in the oxidation of **sugars** is retarded by phosphates. L. Soep found that the **aniline dye**, orange II, in 1 per cent. soln., gives short, yellow needles of a complex which produces polarization colours, and which can be utilized as a micro-chemical test. N. N. Biswas and N. R. Dhar studied the chemiluminescence of aniline dyes, hamatoxylin, etc., in the presence of hydrogen dioxide and ferrous sulphate. E. J. Morgan and J. H. Quastel noted the reduction of **methylene blue** by ferrous sulphate. W. Thomson and F. Lewis studied the action of **india-rubber**.

G. Gore discussed the adsorption of ferrous sulphate from its aq. soln. by powdered **silica**; and R. Riecke, and E. C. Sullivan, the adsorption by **orthoclase**, **clays**, and **china clay**. The iron is thought to be removed as ferric hydroxide whilst the SO_4^{--} -ions remain in soln. O. C. Magstad found that in contact with **zeolites** or soil minerals, the Fe^{++} -ions in aq. soln. of ferrous sulphate are displaced by Ca^{++} -ions, and R. Dollfus observed that a crystal of heptahydrated ferrous sulphate in a soln. of **alkali silicate** produces a column—silica garden—which consists of a skin of ferrous silicate with a soln. of ferrous sulphate inside. J. Tünnermann found that when the heptahydrate is triturated with **borax**, a greyish-yellow product is formed, which, when treated with water, yields a greyish-green precipitate.

Soln. of iron salts are reduced to metal by the more electropositive metals like magnesium, zinc, or aluminium. E. Hils studied the action of **silver**. C. Brückner observed that when a mixture of anhydrous ferrous sulphate and powdered **magnesium** is heated in an indifferent gas, the iron is oxidized and sulphur dioxide, thiosulphate, and sulphide are formed; a black sulphide is formed when the mixture is triturated in a mortar. H. Heinrichs also studied the reaction. A. Commaille, and D. Tommasi observed that a neutral aq. soln. of ferrous sulphate reacts with magnesium forming a precipitate of white ferrous hydroxide which in air soon oxidizes to yellow hydrated ferric oxide; hydrogen is also evolved. Z. Roussin observed that with feebly-acidic soln. of the salt, iron is precipitated, and A. Commaille added that the precipitated iron is immediately redissolved. J. Thomsen said that the replacement of iron by magnesium in ferrous sulphate soln. evolves 87.06 Cals. F. Muck studied the action of **zinc** on soln. of ferrous sulphate. H. Heinrichs found that a mixture of ferrous sulphate and powdered **aluminium** begins to form an oxide at about 600° , the reaction proceeds explosively at 900° , and the sulphate is reduced to sulphide. M. J. Salauze studied the reaction. O. Prelinger observed that iron is precipitated by powdered **manganese** from an aq. soln. of ferrous sulphate. C. W. Kastner found that with powdered **iron**, hydrogen sulphide is evolved from an aq. soln. of ferrous sulphate, and a blue subsulphide is formed; P. Sabatier and J. B. Senderens observed that hydrogen is slowly evolved from the aq. soln. J. A. N. Friend and P. C. Barnet said that a soln. of ferrous sulphate acts on iron more slowly than is the case with water.

M. C. Boswell and J. V. Dickson found that when ferrous sulphate is fused with **sodium hydroxide**, hydrogen is given off eq. to the oxygen taken up by the salt. Anhydrous ferrous oxide reacts with **calcium**, **strontium**, and **barium oxides**: $2\text{FeSO}_4 + \text{CaO} = \text{CaSO}_4 + \text{Fe}_2\text{O}_3 + \text{SO}_2$, and J. A. Hedvall and J. Heuberger observed that the temp. of reaction are respectively 444° , 426° , and 345° ; with moist mixtures, ferrous and ferrosic oxides are also formed. J. N. von Fuchs observed no precipitation occurs when soln. of ferrous salts are treated with **calcium carbonate**—vide ferric sulphate—but H. C. Sorby, and J. P. Kimball showed that an exchange of bases occurs whereby the calcium is replaced by iron. L. Dieulafoy also found that in the presence of iron, manganese, and zinc salt soln., the iron is precipitated first, and then follow zinc and manganese. F. Thomas found that there is a slow reaction with **cuprous oxide** and soln. of ferrous sulphate: $\text{Cu}_2\text{O} + 2\text{FeSO}_4 + \text{O}_2 = 2\text{CuSO}_4 + \text{Fe}_2\text{O}_3$. According to E. Braun, the addition of basic **copper carbonate** to a soln. of ferrous sulphate, produces a dirty green-coloured

precipitate, which, when warmed, turns yellowish-brown, and is thought to be a mixture of cuprous hydroxide and basic ferric sulphate. Cupric hydroxide partially dissolves in a neutral soln. of ferrous sulphate, and the soln. becomes reddish-yellow. W. G. Murray examined the action of 5 per cent. soln. of ferrous sulphate in sea-water and in fresh water, on **oxidized copper ores**—chrysocolla, malachite, and cuprite. In the absence of air, and in a neutral soln., very little copper is dissolved, but with the free access of air, a maximum of 56 per cent. of the total copper dissolved readily, although 98 per cent. was dissolved by acetic acid. The solvent action of ferrous sulphate is attributed to its oxidation to ferric sulphate which behaves as a weak acid, the iron being precipitated as a basic salt by the copper minerals. Malachite is more active than chrysocolla as a precipitant. D. G. Murray, and R. H. Bradford also studied the action of anhydrous ferrous sulphate on copper ores. S. Bodforss found that the Fe^{++} -ions in a soln. of ferrous sulphate are readily displaced by Ba^{++} -ions but not by Be^{++} -ions from **beryllium salts**. I. Sukanuma observed that **aragonite** becomes green by the adsorption of ferrous sulphate from aq. soln., but **calcite** becomes yellow through the formation of a basic sulphate. W. Diesel discussed the adsorption of ammonium ferrous sulphate from its aq. soln. by aragonite, calcite, and **vaterite**. L. Gerstacker found that when the aq. soln. is triturated with **zinc oxide** for half an hour, a dark green colour is produced which gradually darkens. A. Mailhe found that freshly-precipitated **mercuric oxide** gives a mixed precipitate of mercury, mercurous sulphate, and a basic sulphate. F. Bayer extracted the manganese from **manganiferous slags** and ores by heating them under pressure with a soln. of ferrous sulphate.

J. L. Gay Lussac and L. J. Thénard observed that **potassium fluoride** reacts with a soln. of ferrous sulphate forming a white precipitate—probably tetrahydrated ferrous fluoride—which is soluble in a large excess of hydrofluoric acid. A. Ditte showed that when anhydrous ferrous sulphate is melted with **sodium chloride** it does not form crystals of ferric oxide, but with the hydrated sulphate, the crystals are formed. M. von der Ballen reported that when a mixture of the heptahydrate and sodium chloride is gradually heated to redness, hydrogen chloride is evolved and sodium sulphate is formed; but this conclusion was denied by C. F. S. Hahnemann, J. Lieblein, M. Tuhten, and J. C. Wiegler. According to K. H. Oenicke, a mixture of the heptahydrate and sodium chloride, when heated, first gives off water, and a sublimate of ferric chloride is formed; molten sodium chloride was found by G. Rousseau and J. Bernheim to furnish crystals of $\text{Fe}_2\text{O}_3 \cdot \text{H}_2\text{O}$, and, according to C. F. Rammelsberg, and A. Ditte, crystals of ferric oxide. G. Rousseau and J. Bernheim observed that with molten **potassium chloride**, potassium ferrite is formed, and the proportion of combined water is less the higher is the temp. of formation. F. Kuhlmann found that with molten **calcium chloride** in a closed crucible, magnetic ferrous oxide is formed.

Ferrous sulphate forms complex salts with many of the **metal sulphates**—*vide infra*; and it also acts as a mild reducing agent. M. Randall and C. F. Failey found that in the order of salting out of ions, Fe^{++} stands between Mg^{++} and Zn^{++} . H. Frischer, F. Herrmann, and H. C. Biddle found that a soln. of ferrous sulphate reduces an ammoniacal soln. of a **cupric salt** forming a soln. of a cuprous salt and a precipitate of hydrated ferrous oxide. This reaction offers one mode of preparing a soln. of a cuprous salt for carbon monoxide absorptions in gas analyses. P. Rohland observed that a soln. of ferrous sulphate in methyl alcohol reduces cupric salts to cuprous salts. Ferrous sulphate reduces **silver salts** to the metal: $\text{Ag}_2\text{SO}_4 + 2\text{FeSO}_4 = 2\text{Ag} + \text{Fe}_2(\text{SO}_4)_3$; and also $3\text{AgNO}_3 + 3\text{FeSO}_4 = 3\text{Ag} + \text{Fe}_2(\text{SO}_4)_3 + \text{Fe}(\text{NO}_3)_3$. These reactions have been discussed by H. Landolt, A. lo Surdo, W. H. Emmons, A. Heydweiller, Lord Rayleigh, and J. Joly in order to find if there is any appreciable loss of weight during a chemical reaction. L. Pisarschewsky found the equilibrium constant of the reaction: $\text{Ag}_2\text{SO}_4 + 2\text{FeSO}_4 = \text{Fe}_2(\text{SO}_4)_3 + 2\text{Ag}$, at 25° , to be $K = 0.00793$; and M. V. Dover, 0.0070. The reaction is sensitive to light, and there is a small disturbance due to the

hydrolysis of the ferric sulphate soln. N. A. Tananaeff gave $K=0.0018$ at 0° , 0.0061 at 25° , and 0.0110 at 45° ; the heat of the reaction is 7868 cal. per gram-atom of silver—L. Pissarschewsky gave 8685 cal. The reaction was also studied by W. Haehnel, V. Kohlschütter and K. Steck, D. Roberts and F. G. Soper, and R. Luther. The reduction of **gold chloride** by a soln. of ferrous sulphate: $\text{AuCl}_3 + 3\text{FeSO}_4 = \text{Au} + \text{FeCl}_3 + \text{Fe}_2(\text{SO}_4)_3$, is utilized in photographic toning. When an acidified soln. of ferrous sulphate is shaken with **mercurous sulphate**, L. W. McCay and W. T. Anderson represented the reaction: $2\text{FeSO}_4 + \text{Hg}_2\text{SO}_4 \rightleftharpoons \text{Fe}_2(\text{SO}_4)_3 + 2\text{Hg}$. P. Schwarzkopf found that with **mercuric chloride**, and ferrous sulphate soln. no precipitation occurs for many hours, but if some potassium fluoride be added to the soln., mercurous chloride is precipitated in a few minutes. N. R. Dhar observed that in diffused daylight no reaction occurs in a soln. of ferrous sulphate and mercuric chloride, but in sunlight, there is a slow reduction of the mercuric salt. A mixed soln. of mercuric chloride and ammonium oxalate decomposes in light: $2\text{HgCl}_2 + (\text{NH}_4)_2\text{C}_2\text{O}_4 = 2\text{HgCl} + 2\text{NH}_4\text{Cl} + 2\text{CO}_2$. H. C. Winther observed that the sensitiveness of the reaction is dependent on the purity of the salts. Small proportions of iron salts favour the reaction, and it is doubtful if any photochemical action would occur if all traces of iron salts were absent. Again, H. S. Hatfield showed that the liberation of iodine from a soln. of **mercuric iodide** exposed to sunlight does not occur if traces of iron salts be rigorously excluded. T. S. Price showed that a trace of a ferrous salt favours the oxidation of a soln. of **stannous chloride** in air, and the maximum effect is obtained with $\text{FeCl}_2 : \text{SnCl}_2 = 1 : 100$. M. Berthelot discussed the thermal value of the reaction between ferrous sulphate and **ferric chloride** in aq. soln., and similarly with **ferric nitrate**. E. M. Walton showed that when heptahydrated ferrous sulphate is mixed with enneahydrated ferric nitrate, or trihydrated ferric chloride, liquefaction occurs.

C. C. Benson found that the rate of oxidation of ferrous sulphate by **chromic acid** is proportional to the second power of the concentration of both the ferrous salt and the acid. The increase in the rate of oxidation by potassium dichromate is proportional to the 1.7th power of its concentration. She also studied the rate of liberation of iodine from potassium iodide by the action of chromic acid in the presence of ferrous salts. The oxidation of ferrous salts by **potassium dichromate** soln. (*q.v.*) is represented by: $6\text{FeSO}_4 + \text{K}_2\text{Cr}_2\text{O}_7 + 7\text{H}_2\text{SO}_4 = \text{K}_2\text{SO}_4 + \text{Cr}_2(\text{SO}_4)_3 + 3\text{Fe}_2(\text{SO}_4)_3 + 7\text{H}_2\text{O}$. The reaction is utilized in the volumetric determination of iron; and similarly with the oxidation of ferrous salts by **potassium permanganate** (*q.v.*) in acidic soln.: $10\text{FeSO}_4 + 2\text{KMnO}_4 + 8\text{H}_2\text{SO}_4 = 5\text{Fe}_2(\text{SO}_4)_3 + \text{K}_2\text{SO}_4 + 2\text{MnSO}_4 + 8\text{H}_2\text{O}$. The reaction was studied by J. L. Kassner and co-workers. According to E. Müller and H. Möllering, in the electrometric titration of the reaction between ferrous sulphate and potassium permanganate in sulphuric acid soln.: $\text{MnO}_4' + 5\text{Fe}'' + 8\text{H}' = \text{Mn}'' + 5\text{Fe}''' + 4\text{H}_2\text{O}$, the end-potential is 0.65 volt if the permanganate is added to the iron soln., and 0.76 volt if the ferrous salt be added to the permanganate soln., but in hydrochloric acid soln., the respective values are 0.67 volt and 0.66 volt. D. R. Hale studied the reaction between ferrous sulphate, potassium permanganate, and sodium arsenite.

The use of ferrous sulphate as a dressing for crops has been discussed by E. J. Russell, A. B. Griffiths, P. M. Delacharbonny, L. Destremx, and H. Boiret and G. Paturel. Beneficial results follow only when an excess of lime is present whereby calcium sulphate is formed; alone, ferrous salts exert a toxic influence on vegetation, and the sterility of badly aerated soils is attributed in part to the presence of ferrous sulphate. Soln. of ferrous sulphate are more or less toxic, and have been used as weed-killers, fungicides, insecticides, etc. D. L. Belding found ferrous sulphate is but slightly toxic to fish. The soln. are astringent, and have been employed as coagulants, and, according to W. L. Brooke, as a primer before painting resinous woods.

§ 44. The Complex Salts of Ferrous Sulphate

There is a series of important salts represented by the general formula: $R_2SO_4 \cdot FeSO_4 \cdot 6H_2O$, where R represents univalent ammonium, potassium, rubidium, caesium, and thallium. M. Lachaud and C. Lepière¹ reported that with a molten mixture of sulphuric acid and equimolar parts of the two sulphates, ferric sulphate, and the two complex sulphates: $4(NH_4)_2SO_4 \cdot FeSO_4 \cdot Fe_2(SO_4)_3 \cdot 3H_2O$; and $3(NH_4)_2SO_4 \cdot Fe_2(SO_4)_3$; as well as $(NH_4)_2SO_4 \cdot Fe_2(SO_4)_3$, are formed. H. A. von Vogel prepared **ammonium ferrous sulphate**, $(NH_4)_2SO_4 \cdot FeSO_4 \cdot 6H_2O$, or $(NH_4)_2SO_4 \cdot [Fe(H_2O)_6]SO_4$, i.e. *ammonium ferrous hexaquo sulphate*, by allowing a mixed soln. of equimolar parts of ammonium and ferrous sulphates to crystallize; and also a similar soln. of ferrous sulphate and ammonium chloride. C. M. Marx also prepared this salt, and C. F. Mohr showed how to obtain the salt for use in standardizing permanganate and other soln. in volumetric analysis. The salt is often called *Mohr's salt*. O. Aschan obtained the salt by the action of a soln. of ammonium persulphate on iron:

F. A. H. Schreinemakers studied the conditions of equilibrium, and found that at 30°, sat. soln. contained the following proportions by weight—*vide* Fig. 652.

FeSO ₄	24.9	25.24	25.22	25.59	17.64	7.95	0.79	0
(NH ₄) ₂ SO ₄	0	5.24	5.93	6.44	8.90	16.29	43.90	44.27
Solid phases		FeSO ₄ ·7H ₂ O		(NH ₄) ₂ SO ₄ ·FeSO ₄ ·6H ₂ O			(NH ₄) ₂ SO ₄	

The pale green, monoclinic crystals are usually tabular. A. Murmann and L. Rotter gave for the axial ratios, $a : b : c = 0.7466 : 1 : 0.4950$, and $\beta = 106^\circ 48'$;

A. E. H. Tutton gave $0.7377 : 1 : 0.4960$, and $\beta = 106^\circ 50'$. Observations on the crystals were also reported by C. F. Rammelsberg, and E. S. von Fedoroff. The cleavage parallel to $(\bar{2}01)$ is fairly regular throughout the isomorphous series. W. Hofmann found that the X-radiograms show the lattice parameters to be: $a = 9.28 \text{ \AA}$, $b = 12.57 \text{ \AA}$, and $c = 6.22 \text{ \AA}$, and $\beta = 106^\circ 51'$.

FIG. 652.—The Effect of Some Metal Sulphates on the Solubility of Ferrous Sulphate.

E. Mitscherlich, and C. M. Marx found the crystals isomorphous with those of the corresponding magnesium salt; G. Wulff, and C. von Hauer, with the corresponding zinc salt; and A. E. H. Tutton, with the corresponding salts of the alkali metals. S. Meyer found that in the deposition of the crystals from a sat. soln., under the influence of a magnetic field, the shorter diagonal of the tabular crystals coincides with the lines of force. G. Wulff found the relative rates of growth of the faces of the crystals to be in the ascending order $(\bar{2}01)$, (110) , (001) , (111) , $(\bar{1}11)$, and (011) . C. von Hauer, and G. Wulff found that as ammonium ferrous sulphate grows on a crystal of ammonium zinc sulphate, the relative development of the different faces is that just indicated. I. Zweiglowna discussed the isomorphism of this salt with the corresponding magnesium salt; D. Ostersetzer, with the zinc salt; and B. Haber-Chuwis, with the copper salt.

The corrosion figures studied by H. Baumhauer were in agreement with the holohedral, monoclinic symmetry; they are asymmetrical to the single plane of symmetry (010) which is at right-angles to the plane of the paper, and parallel to the longer sides of the page, they also accord with the presence of a diagonal axis of symmetry perpendicular to the plane of asymmetry, *i.e.* parallel to the shorter edges of the page. The topic axial ratios are $\chi : \psi : \omega = 6.2094 : 8.4172 : 4.1749$. The optical character is positive; the optic axial angle $2E$ given by A. Murmann and L. Rotter is $135^\circ 42'$; whilst A. E. H. Tutton gave:

	Li-	C-	Na-	Tl-	Cd-	F-light
$2E$	$133^\circ 8'$	$133^\circ 16'$	$134^\circ 17'$	$135^\circ 12'$	$135^\circ 35'$	$135^\circ 57'$
$2H_a$	$67^\circ 33'$	$67^\circ 30'$	$67^\circ 20'$	$67^\circ 4'$	$66^\circ 55'$	$66^\circ 47'$
$2H_o$	$90^\circ 10'$	$90^\circ 2'$	$89^\circ 33'$	$89^\circ 3'$	$88^\circ 45'$	$88^\circ 29'$
$2V_a$	$76^\circ 16'$	$76^\circ 18'$	$76^\circ 25'$	$76^\circ 28'$	$76^\circ 30'$	$76^\circ 33'$

The apparent angle $2E$ diminishes about 4° when the temp. is raised from 10° to 60° . W. Hofmann obtained X-radiograms of the salt, $(\text{NH}_4)_2\text{Fe}(\text{SO}_4)_2 \cdot 6\text{H}_2\text{O}$, and calculated the lattice constants: $a = 9.28 \text{ \AA}$, $b = 12.58 \text{ \AA}$, $c = 6.22 \text{ \AA}$, and $\beta = 10^\circ 50'$. M. Bentivoglio studied the rate of growth of the crystals.

H. Schiff gave 1.813 for the sp. gr. of the salt; H. G. F. Schröder, 1.886; and L. Playfair and J. P. Joule, 1.848. A. E. H. Tutton gave 1.864 for the sp. gr. at $20^\circ 4'$; and 208.86 for the mol. vol. H. Schiff measured the sp. gr. of aq. soln. of the salt, and G. T. Gerlach recalculated the results, showing that:

$(\text{NH}_4)_2\text{Fe}(\text{SO}_4)_2 \cdot 6\text{H}_2\text{O}$	1	5	10	15	20	25	30 per cent.
Specific gravity	1.006	1.030	1.060	1.092	1.124	1.156	1.193

H. Schiff gave for soln. with p per cent. of $(\text{NH}_4)_2\text{Fe}(\text{SO}_4)_2 \cdot 6\text{H}_2\text{O}$ at 16.5° :

p	26.40	17.60	11.74	8.80	5.87
Sp. gr.	1.1666	1.1083	1.0708	1.0530	1.0354

and he represented the results by: $\text{Sp. gr.} = 1 + 0.005918p + 0.041083p^2 + 0.061715p^3$.

I. Traube gave for the volume change which occurs when the salt is dissolved in water at 16.5° : Percentage anhydrous $(\text{NH}_4)_2\text{Fe}(\text{SO}_4)_2$, 7.245, 10.867, 14.490, and 19.127; with the respective sp. gr., 1.060, 1.092, 1.124, and 1.1666; and the respective vol. changes, 62.1, 63.9, 67.9, and 71.7 units. H. L. Maxwell showed that diffusion experiments indicate that the salt is partially dissociated into its components. C. A. Martius observed the f.p. of soln., and W. A. Kistiakowsky found that the lowerings of the f.p. of soln. of 0.852, 1.798, 3.667, and 7.136 grms. of the hexahydrate in 100 grms. of water were respectively 0.23° , 0.44° , 0.792° , and 1.375° , so that the mol. lowerings were respectively 2.895, 3.238, 3.68, and 4.06. E. Rouyer holds that the ebullioscopic observations indicate the existence of the double salt in soln. at 100° . T. Graham found that the heat of soln., $(\text{NH}_4)_2\text{Fe}(\text{SO}_4)_2 \cdot 6\text{H}_2\text{O} + \text{Aq.} = -9.8 \text{ Cals.}$ A. Murmann and L. Rotter found the indices of refraction, β , for red-, yellow-, and green-light were respectively 1.487, 1.490, and 1.492. A. E. H. Tutton gave:

	Li-	C-	Na-	Tl-	Cd-	F-	G-light
α	1.4839	1.4844	1.4870	1.4896	1.4911	1.4926	1.4971
β	1.4885	1.4890	1.4915	1.4942	1.4957	1.4972	1.5019
γ	1.4957	1.4962	1.4989	1.5017	1.5032	1.5047	1.5094

The β -values for any wave-length λ can be represented by $\beta = 1.4784 + 494204\lambda^{-2} - 885610000000\lambda^{-4} + \dots$. The α -values are reproduced if 1.4784 is reduced by 0.0046, and the γ -indices if it be raised by 0.0074. The raising of the temp. from 10° to 60° lowered the α -values an average of 0.0013, the β -values, 0.0017, and the γ -values 0.0018. The sp. refraction with the μ^2 -formula for α , β , and γ were for the C-ray, respectively 0.1536, 0.1548, and 0.1568, and for the G-ray, respectively 0.1570, 0.1583, and 0.1603; the mol. refractions for the C-ray were 55.61, 56.25, and 57.71 respectively, and for the G-ray respectively 56.78, 57.46, and 58.95. The sp. dispersions, $\mu_\alpha - \mu_\gamma$, are accordingly 0.0034, 0.0035, and 0.0035 respectively,

while the mol. dispersions are respectively 1.17, 1.21, and 1.24. For the *C*-ray, and the μ -formula, the mol. dispersions are respectively 93.78, 95.05, and 97.94. H. Nisi measured the Raman effect. R. Saxon, and M. Ogoshi studied the electrolysis of aq. soln. of the salt—*vide supra*, the preparation of iron. G. Quincke gave 44×10^{-6} mass unit for the magnetic susceptibility of soln. of ammonium ferrous sulphate at 18° , and O. Liebknecht and A. P. Wills, 45×10^{-6} mass unit at 18° . W. Finke observed for the crystals of the hexahydrate, 79×10^{-6} vol. unit. L. A. Welo measured the magnetic susceptibility of solid and molten ammonium ferric sulphate, $\text{NH}_4\text{Fe}(\text{SO}_4)_2 \cdot 12\text{H}_2\text{O}$, and L. C. Jackson's results for the reciprocal of the mol. magnetic susceptibility at different temp. are summarized in Fig. 645. P. Weiss and C. A. Frankamp studied the susceptibility of aq. soln. For the Curie constant, $C = \chi(T - \theta)$, for the solid and liquid states, $C_s = 4.30$; $C_l = 4.43$; $\theta_s = 0^\circ$, and $\theta_l = -173^\circ$. D. E. Olshevsky studied the orientation of the crystals in a magnetic field; and L. Pauling and M. L. Huggins, the magnetic properties.

Ammonium ferrous sulphate is stable at ordinary temp., and the cold soln. do not readily oxidize, so that it is used for standardizing permanganate soln. C. Baskerville and R. Stevenson found no oxidation occurred when a stream of air was passed for 3 hrs. through an aq. soln. of Mohr's salt acidified with sulphuric acid. They observed no catalytic effects with salts of cobalt, chromium, copper, and manganese—but see ferrous sulphate, above. H. A. von Vogel found that the crystals effloresce a little above 100° , and when heated, they swell up to a white mass, without fusion, and give off water, ammonia, and ammonium sulphate. Sulphuric acid abstracts water from the crystals and makes them opaque. Mohr's salt is less soluble in water than ferrous sulphate. E. Tobler gave for the solubility, *S* grms. of the hexahydrate in 100 grms. of water:

	0°	15°	40°	50°	70°
<i>S</i>	12.5	20.0	33.0	40	52

J. Locke found 351 grms. of the anhydrous salt dissolve in a litre of water at 25° . F. A. H. Schreinemakers stated that the salt is soluble in water without decomposition—the aq. soln. at 30° contains 13.13 per cent. of FeSO_4 , and 11.45 per cent. of ammonium sulphate. M. T. Salazar and E. Moles observed no signs of hydrolysis in the aq. soln. W. Finke found the magnetic susceptibilities in the three crystallographic directions to be for *a*, *b*, and *c*, respectively, 85.48×10^{-6} , 75.67×10^{-6} , and 74.90×10^{-6} mass unit. S. Kitajima found that the hydrolysis, represented by the acid concentration at 20° to 25° , was:

Concentration	2	5	10	15	20	25	30	50 per cent.
Acidity	0.00428	0.00556	0.00707	0.00752	0.00675	0.00669	0.00650	0.00625N

E. Weitz and H. Müller prepared the amino-analogue of Mohr's salt, namely, **ammonium ferrous aquopentamminosulphate**, $(\text{NH}_4)_2\text{SO}_4 \cdot [\text{Fe}(\text{H}_2\text{O})(\text{NH}_3)_5]\text{SO}_4$. Like ferrous sulphate, soln. of this salt readily absorb nitric oxide. W. Eidmann found that the salt is not soluble in acetone. B. V. Nekrasoff studied the absorption of the salt from aq. soln. by charcoal. N. R. Dhar observed that the reaction between silver nitrate and ammonium ferrous sulphate is bimolecular and very rapid at 0° with a small temp. coeff. In due course a state of equilibrium: $\text{Ag} + \text{Fe}(\text{NO}_3)_3 \rightleftharpoons \text{AgNO}_3 + \text{Fe}(\text{NO}_3)_2$, is established. The reaction is accelerated by nitric, sulphuric, citric, tartaric, acetic, and carbonic acids, but not by boric acid nor phenol; and it is retarded by manganese salts and potassium nitrate.

According to D. Linck, E. Mitscherlich, D. Brewster, and J. C. G. de Marignac, if a soln. of equimolar proportions of potassium and ferrous sulphates be evaporated at ordinary temp., green crystals of **potassium ferrous sulphate**, $\text{K}_2\text{SO}_4 \cdot \text{FeSO}_4 \cdot 6\text{H}_2\text{O}$, are formed; and if a soln. of iron filings in one of potassium hydrosulphate be similarly treated, the *hexahydrate* is similarly formed. O. Aschan obtained the salt by the action of a soln. of potassium persulphate on iron. R. M. Caven and J. Ferguson studied the vap. press. of aq. soln., and noted that the hexahydrate

passes into the tetrahydrate which has a dissociation press. of 85.9 mm. at 50°. F. W. Küster and A. Thiel found that when a soln. of equimolar proportions of the two salts crystallizes between 35° and 85°, pale green crystals of the *tetrahydrate*, $K_2SO_4 \cdot FeSO_4 \cdot 4H_2O$, are formed, and above 90°, colourless crystals of the *dihydrate*, $K_2SO_4 \cdot FeSO_4 \cdot 2H_2O$, are formed. The transition temp. for the hexa- and tetra-hydrates is 30°; for the tetra- and di-hydrates, 87°; and for the hexa- and di-hydrates, 54°, as indicated in Fig. 653. The solubility curves, expressed in terms of the c.c. of 0.1N- $KMnO_4$, is required for 2 c.c. of the soln. of the double salt, are given in Fig. 653; and when re-calculated to show S grms. of $K_2SO_4 \cdot FeSO_4$ per 100 c.c. of soln., the solubilities of the different hydrates are :

	0.5°	17.2°	40.1°	60.0°	80.0°	90.0°	95.0°
S { 6-hydrate . . .	19.72	27.04	39.45	46.13	48.68	—	—
4-hydrate . . .	24.66	28.79	34.84	38.34	43.43	47.09	47.41
2-hydrate . . .	24.50	34.36	43.91	45.82	45.50	45.98	44.07

J. C. G. de Marignac, and G. Wyrouboff prepared green, tabular crystals of the dihydrate by cooling the soln. rapidly from 60°. The green triclinic crystals have the axial ratios $a : b : c = 0.7113 : 1 : 0.4501$, and $\alpha = 85^\circ 16'$, $\beta = 102^\circ 18'$, and $\gamma = 86^\circ 48'$. The crystals are isomorphous with the corresponding manganous salt. Twinning occurs about the (010)-plane, and the (101)-cleavage is complete, but the (001)-cleavage is incomplete. The optical character is negative, and the optic axial angle $2E = 96^\circ$. The sp. gr. is 2.683. The crystals become matt on exposure to air owing to the absorption of moisture.

A. E. H. Tutton obtained green, transparent crystals of the hexahydrate by slow crystallization over conc. sulphuric acid, in vacuo. The crystals are liable to effloresce in vacuo, and, in consequence, should be removed soon after they are formed. J. C. G. de Marignac, H. de Sénarmont, and A. Murmann and L. Rotter examined the crystals of the hexahydrate, and found the monoclinic prisms to be isomorphous with ammonium cobaltous sulphate. According to A. E. H. Tutton, the monoclinic prisms have the axial ratios $a : b : c = 0.7377 : 1 : 0.5020$, and $\beta = 104^\circ 32'$; and the topic axial ratios $\chi : \psi : \omega = 6.0739 : 8.2336 : 4.1332$. The cleavage parallel to (201) is well defined. The optical character is positive. The optic axial angles are :

	Li-	C-	Na-	Tl-	F-light
$2H_a$. . .	66° 52'	66° 52'	66° 55'	66° 57'	67° 2'
$2H_o$. . .	112° 38'	112° 39'	112° 27'	112° 17'	112° 2'
$2V_a$. . .	67° 1'	67° 2'	67° 7'	67° 12'	67° 19'
$2E$. . .	109° 37'	109° 41'	110° 10'	110° 35'	111° 51'

FIG. 653.—Solubility of Potassium Ferrous Sulphate.

Observations were also made by A. Murmann and L. Rotter, and H. Topsöe and C. Christiansen; the latter gave $2V = 67^\circ 78'$, and $2E = 110^\circ 32'$ for the D -line. A. E. H. Tutton observed that the apparent axial angle in air is increased about 2° for each rise of temp. up to 50° , at which temp., the crystals become opaque. H. Schiff gave 2.18 for the sp. gr. of the hexahydrate, L. Playfair and J. P. Joule gave 2.202. H. G. F. Schröder gave 3.042 for the sp. gr. of the anhydrous salt, whilst A. E. H. Tutton found 2.1694 at $20^\circ/4^\circ$ for the sp. gr., and 200.09 for the mol. vol. R. M. Caven and J. Ferguson found that the dissociation press. of potassium ferrous sulphate, p mm., is :

	25.1°	39.0°	50.7°	61.7°	71.5°
p . . .	21.0	48.3	89.1	148.6	228.9

and the data can be represented by $\log p = 6.768 - 866.5T^{-1} - 244400T^{-2}$. The heat of hydration of the tetrahydrate per mol. of water vapour is 10.4 Cals. T. Graham

found that the heat of soln. is -10.7 Cals. A. E. H. Tutton gave for the mean refractive indices :

	Li-	C-	Na-	Tl-	F-	G-light
α . . .	1.4731	1.4735	1.4759	1.4782	1.4811	1.4852
β . . .	1.4795	1.4799	1.4821	1.4847	1.4877	1.4920
γ . . .	1.4941	1.4945	1.4969	1.4995	1.5028	1.5071

H. Topsøe and C. Christiansen found for C-, Na-, and F-light, the respective values $\alpha=1.4751$, 1.4775 , and 1.4833 ; $\beta=1.4806$, 1.4832 , and 1.4890 ; and $\gamma=1.4947$, 1.4973 , and 1.5041 . A. Murmann and L. Rotter gave $\beta=1.478$ for red-light; 1.480 for yellow-light; 1.484 for green light; and 1.489 for violet-light. A. E. H. Tutton represented the vacuum values of β , for light of wave-length λ as far as F, by $\beta=1.4728+266439\lambda^{-2}+243790000000\lambda^{-4}+\dots$; and if 1.4728 be altered to 1.4664 it represents the value of α , and if changed to 1.4875 , values of γ . The indices at 55° were about 0.0010 lower than at ordinary temp. The sp. refractions by the μ^2 -formula for α , β , and γ for the C-line are respectively 0.1296 , 0.1301 , and 0.1344 , and for the G-line, respectively 0.1323 , 0.1339 , and 0.1373 ; the corresponding mol. refractions for the C-line are respectively 56.22 , 56.87 , and 58.34 , and for the G-line respectively 57.41 , 58.09 , and 59.60 . The sp. dispersions $\mu_G-\mu_C$, are respectively 0.0027 , 0.0029 , and 0.0029 , with the corresponding mol. dispersions, 1.19 , 1.22 , and 1.26 respectively. The mol. refractions by the μ -formula, and the C-line are 94.82 , 96.10 , and 99.03 respectively for α , β , and γ . These values are almost constant for the range of temp. in which the salt can exist. I. I. Rabi observed that the crystals are paramagnetic; and K. S. Krishnan and co-workers studied the magnetic properties. Y. Ono studied the oxidation of a mixed soln. of ammonium ferrous sulphate and ammonium oxalate by potassium permanganate. S. Miyamoto studied the effect of hydrogen and the silent discharge on the salt.

H. G. F. Schröder gave 3.042 for the sp. gr. of the anhydrous salt obtained by fusing together the correct proportions of the component salts. F. Ephraim and P. Wagner discussed the mol. vol. J. C. G. de Marignac said that the crystals of the hexahydrate form potassium sulphate and ferric oxide when heated in air. E. Tobler gave for the solubility S grms. of the anhydrous salt per 100 grms. of water—*vide supra* :

	0°	10°	14.5°	16°	25°	35°	40°	55°	65°	70°
S . . .	19.6	24.5	29.1	30.9	36.5	41	45	56.1	59.3	64.2

A. E. H. Tutton prepared pale green, transparent crystals of **rubidium ferrous sulphate**, $\text{Rb}_2\text{SO}_4 \cdot \text{FeSO}_4 \cdot 6\text{H}_2\text{O}$, by the method employed for the potassium salt. The monoclinic crystals have the axial ratios $a:b:c=0.7377:1:0.5004$, and $\beta=105^\circ 44'$. Observations were also made by F. L. Perrot. A. E. H. Tutton gave for the topic axial ratios $\chi:\psi:\omega=6.1832:8.2817:4.1942$. The (201) -cleavage is perfect. The optical character is positive. The optic axial angles :

	Li-	C-	Na-	Tl-	F-light
$2H_a$. . .	$73^\circ 5'$	$73^\circ 3'$	$72^\circ 56'$	$72^\circ 48'$	$72^\circ 35'$
$2H_o$. . .	$105^\circ 54'$	$105^\circ 50'$	$105^\circ 41'$	$105^\circ 32'$	$105^\circ 21'$
$2V_a$. . .	$73^\circ 24'$	$73^\circ 23'$	$73^\circ 21'$	$73^\circ 18'$	$73^\circ 13'$
$2E$. . .	$124^\circ 42'$	$124^\circ 49'$	$125^\circ 12'$	$125^\circ 41'$	$126^\circ 16'$

A. E. H. Tutton said that the optic axial angle increases about 1° per 50° rise of temp. F. L. Perrot gave 2.51 for the sp. gr. at 15° , and A. E. H. Tutton, 2.516 at $20^\circ/4^\circ$, and 209.22 for the mol. vol. F. Ephraim and P. Wagner discussed the mol. vol. A. E. H. Tutton found that the mean refractive indices are :

	Li-	C-	Na-	Tl-	F-	G-light
α . . .	1.4789	1.4793	1.4815	1.4839	1.4870	1.4916
β . . .	1.4847	1.4851	1.4874	1.4898	1.4929	1.4973
γ . . .	1.4949	1.4953	1.4977	1.5003	1.5034	1.5080

F. L. Perrot gave a set of values from which, for the D-line, $\alpha=1.4812$, $\beta=1.4870$,

and $\gamma=1.4978$. A. E. H. Tutton gave for β for any wave-length λ , as far as F , $\beta=1.4747+508396\lambda^{-2}-186310000000\lambda^{-4}+\dots$, and if 1.4747 be diminished by 0.0059, the α -indices are reproduced, and if it be increased by 0.0103, the γ -indices. At 60° , the indices are about 0.0014 lower than they are at ordinary temp. The sp. refractions, with the μ^2 -formula for α , β , and γ , with the C -line, are respectively 0.1128, 0.1140, and 0.1160, and with the G -line, respectively 0.1153, 0.1164, and 0.1186; the corresponding mol. refractions with the C -line, respectively 59.40, 60.02, and 61.09; and with the G -line, respectively 60.70, 61.30, and 62.41. The sp. dispersions $\mu_G-\mu_C$, for α , β , and γ , are respectively 0.0025, 0.0024, and 0.0026, and the mol. dispersions respectively 1.30, 1.28, and 1.32. The mol. refractions, by the μ -formula, are respectively 100.36, 101.58, and 103.71. J. Locke found that 0.579 mol or 242 grms. of the anhydrous salt dissolve in a litre of water at 25° . R. M. Caven and J. Ferguson studied the vap. press. of aq. soln.

A. E. H. Tutton also prepared pale green, transparent crystals of **cæsium ferrous sulphate**, $\text{Cs}_2\text{SO}_4 \cdot \text{FeSO}_4 \cdot 6\text{H}_2\text{O}$, by the method used for the potassium salt. The monoclinic crystals have the axial ratios $a:b:c=0.7261:1:0.4953$, and $\beta=106^\circ 52'$; while the topic axial ratios $\chi:\psi:\omega=6.2799:8.6487:4.2837$. The (201)-cleavage is complete. The optical character is positive; and the optic axial angles are:

	Li-	C-	Na-	Tl-	F-light
$2H_a$	$67^\circ 10'$	$67^\circ 5'$	$66^\circ 43'$	$66^\circ 16'$	$65^\circ 43'$
$2H_o$	$92^\circ 12'$	$92^\circ 7'$	$91^\circ 50'$	$91^\circ 30'$	$91^\circ 3'$
$2V_a$	$75^\circ 2'$	$75^\circ 0'$	$74^\circ 51'$	$74^\circ 42'$	$74^\circ 31'$

$2E$ for the Na-line is $132^\circ 47'$. There is a decrease of about $1\frac{1}{2}^\circ$ for a rise of 50° in temp. The sp. gr. at $20^\circ/4^\circ$ is 2.7909, and the mol. vol. 222.64. F. Ephraim and P. Wagner discussed the mol. vol. A. E. H. Tutton found that the indices of refraction are:

	Li-	C-	Na-	Tl-	F-	G-light
α	1.4976	1.4980	1.5003	1.5028	1.5061	1.5105
β	1.5007	1.5011	1.5035	1.5061	1.5093	1.5137
γ	1.5065	1.5069	1.5094	1.5121	1.5153	1.5198

The value of the β -index for any wave-length λ as far as F is $\beta=1.4911+462915\lambda^{-2}-645800000000\lambda^{-4}+\dots$, and if 1.4911 is diminished by 0.0032, the formula represents the α -indices, and if increased by 0.0059, the γ -indices. At 70° , the indices are lower by about 0.0017 than they are at ordinary temp. The sp. refractions with the μ^2 -formula, for α , β , and γ , with the C -line are respectively 0.1051, 0.1057, and 0.1067, and with the G -line, 0.1073, 0.1079, and 0.1090; whilst the corresponding mol. refractions for the C -line are respectively 65.31, 65.65, and 66.29; and for the G -line, 66.69, 67.04, and 67.71. The sp. dispersions, $\mu_G-\mu_C$, are respectively 0.0022, 0.0022, and 0.0023, and the mol. dispersions, respectively 1.38, 1.39, and 1.42. The mol. refractions by the μ -formula are respectively 111.01, 111.70, and 112.90. J. Locke found that 1.967 mols or 1011 grms. of the anhydrous salt dissolve in a litre of water at 25° . This high solubility is in marked contrast with the low solubility of ferric cæsium-alum. R. M. Caven and J. Ferguson studied the vap. press. of aq. soln.

A. E. H. Tutton compared the axial angles of the ammonium, potassium, rubidium, and cæsium salts, and observed that if the first member be excepted, the axial angle, β , steadily increases with the mol. wt., while the axial ratios of the first three salts are very close, those of the cæsium salt are exceptional. Similarly with the sp. gr. and mol. vol. By interchanging rubidium for ammonium, very little change occurs in the mol. vol. in spite of the fact that two atoms of rubidium are replaced by the ten nitrogen and hydrogen atoms of ammonium. The sp. gr. increase with the mol. wt., and likewise also the mol. vols. if ammonium be excepted.

F. A. H. Schreinemakers did not observe the formation of a **lithium ferrous sulphate** in his study of the ternary system: $\text{FeSO}_4\text{-Li}_2\text{SO}_4\text{-H}_2\text{O}$, at 30° , Fig. 652. The solubilities in percentages by weight are:

FeSO ₄	.	.	24.87	22.45	16.18	16.04	15.39	12.68	5.32	0
Li ₂ SO ₄	.	.	0	4.00	16.52	16.49	16.80	18.31	22.15	25.1
Solid phase			FeSO ₄ ·7H ₂ O		FeSO ₄ ·7H ₂ O + Li ₂ SO ₄ ·H ₂ O		Li ₂ SO ₄ ·H ₂ O			

F. A. H. Schreinemakers also studied the quaternary system: FeSO₄-Li₂SO₄-(NH₄)₂SO₄-H₂O at 30°, and found the ranges of stability for the complex salts Li₂SO₄·(NH₄)₂SO₄, and FeSO₄·(NH₄)₂SO₄·6H₂O. J. C. G. de Marignac obtained pale green crystals of **sodium ferrous sulphate**, Na₂SO₄·FeSO₄·4H₂O, by evaporation of a soln. of equimolar proportions of the component salts at 35° or over. O. Aschan obtained the salt by the action of a soln. of sodium persulphate on iron. The monoclinic prisms have the axial ratios $a:b:c=1.3494:1:0.6693$, and $\beta=100^\circ 27'$. J. Koppel's observations on the system: Na₂SO₄-FeSO₄-H₂O are summarized in Figs. 654 and 655. Corresponding soln. are designated with similar letters in both diagrams, those without a dash refer to ferrous sulphate soln., and those with a dash to soln. of sodium sulphate. The curves *FG*, and *F'G'* refer

FIGS. 654 and 655.—The Mutual Solubilities of Sodium and Ferrous Sulphates.

to the solubilities of mixtures of the component sulphates: *MI* and *M'I'*, to the solubility of the complex salt Na₂SO₄·FeSO₄·4H₂O; *GH* and *G'H'*, to that of a mixture of the complex salt and FeSO₄·7H₂O; *GKL* and *G'K'L'*, to that of a mixture of the complex salt and Na₂SO₄·10H₂O or Na₂SO₄; *OAB*, to the solubility of ferrous sulphate; *PCDE*, to the solubility of sodium sulphate; *A*, to the eutectic of FeSO₄·7H₂O and water; and *C*, to the eutectic of Na₂SO₄·10H₂O and water. The temp. of formation of the complex salt, Na₂Fe(SO₄)₂·4H₂O, is 18.5°; in the presence of the double salt, the transformation Na₂SO₄·10H₂O ⇌ Na₂SO₄ + 10H₂O occurs at 31.4°. The eutectic of FeSO₄·7H₂O and ice occurs at -2°; and that of FeSO₄·7H₂O and Na₂SO₄·10H₂O at -3°. The transformation equation at *G*, or *G'*, is Na₂SO₄·10H₂O + FeSO₄·7H₂O = 0.56Na₂Fe(SO₄)₂·4H₂O + 0.077Na₂SO₄·10H₂O + solution 0.14(100H₂O + 2.6Na₂SO₄ + 3.15FeSO₄).

A. and H. Benrath examined the system Na₂SO₄-FeSO₄-H₂O at 97°. The following is a selection from the results for the solution, where the proportions of ferrous and sodium sulphates are expressed in percentages by weight; *x* denotes the mol. proportion of FeSO₄ in the mixture, and *M*, the number of mols. of water per mol. of salt:

FeSO ₄	.	0	1.46	2.35	3.94	6.54	7.32	11.20	18.47	19.57 per cent.
Na ₂ SO ₄	.	30.50	29.09	28.11	27.17	24.91	22.87	19.22	1.92	0
<i>x</i>	.	0	4.48	7.24	11.93	19.60	23.00	35.28	89.90	100.00
<i>M</i>	.	18.00	18.00	18.11	17.62	17.45	18.53	18.51	32.74	34.70
Solid phases:		Na ₂ SO ₄		FeSO ₄ ·3Na ₂ SO ₄		Na ₂ SO ₄ ·FeSO ₄ ·2H ₂ O		FeSO ₄ ·H ₂ O		

The results are summarized in Fig. 656. At this temp. the *tetrahydrate* indicated above does not appear, but there is the *dihydrate*, $\text{Na}_2\text{SO}_4 \cdot \text{FeSO}_4 \cdot 2\text{H}_2\text{O}$, as well as **sodium ferrous tetrasulphate**, $3\text{Na}_2\text{SO}_4 \cdot \text{FeSO}_4$.

The pseudonymous writer, Basil Valentine, in his *Lettes Testament* (Strassburg, 1651), referred to a mixed vitriol of copper and iron; and in 1715, J. F. Henckel² also showed that intimate mixtures of the two vitriols are formed when they crystallize together. J. B. L. Romé de l'Isle, also, referred to what he called *les vitriols mixtes*, and showed that the intimate mixture of iron and copper vitriols furnishes *cubes rhomboïdaux*. The mixed vitriols were also discussed by J. J. Bernhardt, F. S. Beudant, H. D. A. Ficinus, F. Heeren, W. H. Wollaston, A. J. M. Brochant de Villiers, A. Arzruni, E. Mitscherlich, A. G. Monnet, N. Leblanc, E. Wohlwill, L. de Boisbaudran, etc. The isomorphous mixture is sometimes formed when the vitriol has been made from cupriforous pyrites. E. Mitscherlich showed that those crystals which have the form of green vitriol are heptahydrated; and F. S. Beudant said that the crystals have the form of heptahydrated ferrous sulphate if they contain 9 per cent. or more of the salt; and if less than 9 per cent., the crystals resemble those of pentahydrated cupric sulphate. Their colour inclines to green or blue in proportion as the iron or copper predominates. J. W. Retgers observed that soln. of pentahydrated cupric sulphate and heptahydrated ferrous sulphate furnish two kinds of solid soln. He obtained a continuous isomorphous series of monoclinic crystals with from 0 to 53.17 per cent. of heptahydrated cupric sulphate and 46.83 to 100 per cent. of heptahydrated ferrous sulphate; and isomorphous mixtures of triclinic crystals with 94.88 to 100 per cent. of pentahydrated cupric sulphate and 5.12 to 0 per cent. of pentahydrated ferrous sulphate. This subject was also discussed by W. Stortenbeker; and cupriforous melanterite from Cyprus was described by M. H. Hey.

Solid soln. of copper and ferrous sulphates occur in nature in bright blue concretionary or stalactitic forms, and occasionally in crystals. F. Pisani observed one in a copper mine in Turkey; and C. Hintze, one in the mines near Massa Marittima, Tuscany; H. F. Collins, in the Rio Tinto mines of Spain where it was formed by the oxidation of cupriforous pyrites; and W. T. Schaller, near Leona Heights, and at Gonzales, California. There is no definite relation between the proportion of the iron and copper. W. T. Schaller, H. F. Collins, W. F. Hillebrand, F. R. van Horn, H. Leitmeier, C. Hintze, and W. Herz, reported analyses of the mineral. J. W. Retgers said that the mineral is not homogeneous, and the analyses must be represented by the formula: $(\text{Fe,Cu})\text{SO}_4 \cdot 7\text{H}_2\text{O}$. A. Descloizeaux called it *cuproferrite*; M. Adam, *cyanoferferrite*; and G. A. Kenngott, **pisanite**. G. Vavrinecz analyzed the mineral. A. Descloizeaux found that the monoclinic crystals have the axial ratios $a:b:c=1.1609:1:1.5110$, and $\beta=74^\circ 38\frac{1}{2}'$; the (001)-cleavage is easy. The optical character is positive; and C. Hintze gave for the optical axial angles in red-light, $2H_a=86^\circ 8'$, and $2H_o=94^\circ 25'$; in yellow-light, $2H_a=85^\circ 52'$, and $2H_o=94^\circ 59'$; and in green light, $2H_a=65^\circ 3'$, and $2H_o=95^\circ 31'$. W. Herz reported a green, bluish-green, or blue salt from the Salvador Mine, Calama, Chile, and he called it **salvadorite**. Its composition is like that of pisanite, but its optical orientation is different. The monoclinic crystals occur in aggregates of rough prismatic crystals. Twinning occurs. The (010)-cleavage is perfect. E. S. Larsen gave for the monoclinic crystals of pisanite, $\alpha=1.472$, $\beta=1.479$, and $\gamma=1.487$. E. S. Larsen and M. L. Glenn observed the occurrence of pale greenish-blue monoclinic crystals forming columnar masses consisting of microscopic rods not sensibly pleochroic. They called the mineral **copper-melanterite**, $(\text{Zn,Cu,Fe})\text{SO}_4 \cdot 7\text{H}_2\text{O}$. The biaxial crystals have the optic axial angle $2V$ nearly

FIG. 656.—Equilibrium in the System : $\text{Na}_2\text{SO}_4\text{--FeSO}_4\text{--H}_2\text{O}$, at 97° .

100°; the optical character is negative; the sp. gr. is 2.02; the hardness is 2.0; and the refractive indices, $\alpha=1.479$, $\beta=1.483$, and $\gamma=1.488$. They also observed pale green, triclinic crystals of **iron-chalcanthite**, $(\text{Fe,Cu})\text{SO}_4 \cdot 5\text{H}_2\text{O}$. The optical character was negative; the optic axial angle $2V$, moderately large; the indices of refraction, $\alpha=1.517$, $\beta=1.536$, and $\gamma=1.543$; and the dispersion, $\gamma-\alpha=0.026$. E. S. Larsen gave 1.9 for the sp. gr. of pisanite, and H. Leitmeier, 1.950.

It is doubtful if **copper ferrous sulphate** as a chemical individual has been prepared. The products behave like solid soln. A. Étard treated a conc. soln. of copper and ferrous sulphates with a large excess of conc. sulphuric acid in the cold, and obtained small, brick-red crystals approximating $\text{CuSO}_4 \cdot \text{FeSO}_4 \cdot 2\text{H}_2\text{O}$. When heated they become violet, and lose their combined water. A. Scott mixed 100 grms. of pentahydrated ferrous sulphate, 90 grms. of pentahydrated copper sulphate, and 200 c.c. of water, and added 170 c.c. of conc. sulphuric acid to the filtered soln. The homogeneous crystals were yellowish-brown, and approximated in composition $\text{CuSO}_4 \cdot 2\text{FeSO}_4 \cdot 3\text{H}_2\text{O}$. They were non-hygroscopic under ordinary conditions, but water is absorbed from a warm, humid atmosphere. When the crystals are gently heated, they become chocolate-brown and then mauve. The original colour is restored on exposing the crystals to air. C. von Hauer obtained crystals approximating $\text{CuSO}_4 \cdot 2\text{FeSO}_4 \cdot 21\text{H}_2\text{O}$, isomorphous with the corresponding cobalt salt. Some varieties of pisanite were found by W. T. Schaller to have this formula. J. Lefort, and J. Nicklès obtained crystals of $\text{CuSO}_4 \cdot 3\text{FeSO}_4 \cdot 28\text{H}_2\text{O}$ from a soln. containing these proportions of the component salts. They lose water in air, and over conc. sulphuric acid. They begin to melt in their water of crystallization at 100°, and lose 24 mols. of water at 100° to 120°, and the remainder at 300°. 100 parts of water at 7° dissolve 75 parts of the salt, and more is dissolved at a higher temp. G. Agde and H. Barkholt showed that mixed soln. of the two salts do not furnish triclinic solid soln. consisting of 95 to 100 per cent. $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$ and 5 to 0 per cent. $\text{FeSO}_4 \cdot 5\text{H}_2\text{O}$; the solid phase in equilibrium with a soln. containing 35 to 40 per cent. of copper sulphate and less than 6 per cent. of ferrous sulphate is pure $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$. From soln. richer in iron, the monoclinic solid soln. containing 61 to 62 per cent. $\text{CuSO}_4 \cdot 7\text{H}_2\text{O}$, crystallizes out on evaporation or cooling. On the ferrous sulphate side a continuous series of monoclinic solid soln. containing $\text{CuSO}_4 \cdot 7\text{H}_2\text{O}$ and $\text{FeSO}_4 \cdot 7\text{H}_2\text{O}$ in molecular ratios varying from 1 : 50 to 1 : 0.66 crystallizes out. The latter is identical with the double salt described by F. Pisani as $3\text{CuSO}_4 \cdot 7\text{H}_2\text{O}$, $2\text{FeSO}_4 \cdot 7\text{H}_2\text{O}$; but it appears not to be a true double salt, but simply the limiting solid soln. Re-crystallization of mixed crystals of any composition invariably yields crystals poorer in copper sulphate and a correspondingly richer mother-liquor. F. K. Cameron and H. D. Crockford measured the mutual solubilities of the two sulphates in water and obtained for the weights of the respective salts in 100 grms. of water :

25°	{	CuSO_4	22.61	18.37	15.76	11.18	8.48	3.03
		FeSO_4	13.08	13.55	16.04	19.82	22.28	26.61
30°	{	CuSO_4	23.53	21.56	20.54	18.95	16.02	
		FeSO_4	3.13	6.86	17.16	19.61	22.75	
40°	{	CuSO_4	31.68	28.78	21.92	16.89	10.30	3.71
		FeSO_4	22.14	72.47	20.94	25.07	31.46	37.09

The results are plotted in Fig. 657—*vide* Fig. 640. The presence of sulphuric acid lowers the solubility of either salt. For various mixtures of the two salts in sulphuric acid and water, the composition of the solid phases in equilibrium with the soln. corresponds with mixtures of pentahydrated cupric sulphate, $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$, and of acid ferrous sulphates, $\text{FeSO}_4 \cdot n\text{H}_2\text{SO}_4 \cdot \text{H}_2\text{O}$. E. B. Eckel, W. Schrenzlawa, and B. Haber-Chuwis studied solid soln. of the two sulphates. The complex $3(\text{CuSO}_4 \cdot 7\text{H}_2\text{O}) + 2(\text{FeSO}_4 \cdot 7\text{H}_2\text{O})$, described by F. Pisani as occurring in a Turkish mine in the form of stalactites, was not observed.

The colour of A. Étard's, and A. Scott's preparations is curious if the salts are

really solid soln. Monohydrated ferrous sulphate is white, and that of copper sulphate, pale blue. A. J. Allmand found that the colour of the homogeneous solid soln. increases in depth from both ends of the series reaching a maximum where 18 per cent. Fe and 16 per cent. of Cu are present. A very small quantity of ferric iron is always present, being formed as an impurity in virtue of the reaction: $2\text{CuSO}_4 + 2\text{FeSO}_4 = \text{Cu}_2\text{SO}_4 + \text{Fe}_2(\text{SO}_4)_3$; the salts are always slightly basic even when formed in acidic soln. The deficiency of "SO₄" is attributed to the hydrolysis of the ferric sulphate. Cupric sulphate dissolves in solid ferrous sulphate in the form of normal molecules up to about 75 per cent., and thereafter polymerization occurs. A. J. Allmand inferred that the colour is not due to ferric salts or to cuprous salts, but rather to an oscillation of electrons due to the presence of metals in different stages of oxidation. Ferric ferrocyanide and ferrous ferricyanide are also coloured, and similar conditions there prevail.

H. Vohl obtained pale blue, monoclinic columns and plates of **ammonium copper ferrous sulphate**, $2(\text{NH}_4)_2\text{SO}_4 \cdot \text{CuSO}_4 \cdot \text{FeSO}_4 \cdot 12\text{H}_2\text{O}$, by crystallization from a soln. of the component salts; he also obtained, in a similar way, crystals of **potassium copper ferrous sulphate**, $\text{K}_2\text{SO}_4 \cdot \text{CuSO}_4 \cdot \text{FeSO}_4 \cdot 12\text{H}_2\text{O}$. The products, however, are isomorphous mixtures or solid soln.

G. Klatzo³ reported that when a soln. of equimolar parts of beryllium and ferrous sulphates in water, acidified with sulphuric acid, is evaporated, pale blue, monoclinic crystals of **beryllium ferrous sulphate**, $\text{BeSO}_4 \cdot 2\text{FeSO}_4 \cdot 35\text{H}_2\text{O}$, are first deposited, and afterwards colourless monoclinic crystals of $3\text{BeSO}_4 \cdot \text{FeSO}_4 \cdot 28\text{H}_2\text{O}$. P. B. Sarkar and N. Ray prepared **ammonium beryllium ferrous fluosulphate**, $(\text{NH}_4)_2\text{BeF}_4 \cdot \text{FeSO}_4 \cdot 6\text{H}_2\text{O}$. H. Schiff prepared **magnesium ferrous sulphate**, $\text{MgSO}_4 \cdot \text{FeSO}_4 \cdot 14\text{H}_2\text{O}$, by evaporation from a mixed soln. of equimolar proportions of the constituent salts. The greenish-white crystals have a sp. gr. 1.733. The salt was studied by T. V. Barker, and observations on the solid soln. of the two salts were discussed in connection with the crystals of ferrous sulphate. H. Vohl also found that crystals of **potassium magnesium ferrous sulphate**, $2\text{K}_2\text{SO}_4 \cdot \text{MgSO}_4 \cdot \text{FeSO}_4 \cdot 12\text{H}_2\text{O}$, are deposited from a mixed soln. of the three component salts; and similarly with **ammonium magnesium ferrous sulphate**, $2(\text{NH}_4)_2\text{SO}_4 \cdot \text{MgSO}_4 \cdot \text{FeSO}_4 \cdot 12\text{H}_2\text{O}$, and with $4(\text{NH}_4)_2\text{SO}_4 \cdot \text{MgSO}_4 \cdot 3\text{FeSO}_4 \cdot 24\text{H}_2\text{O}$. These products are probably isomorphous mixtures. The solid soln. of the heptahydrates of magnesium and ferrous sulphates were studied by C. F. Rammeisberg. J. W. Retgers showed that with mixed soln. of the heptahydrates of magnesium and ferrous sulphates, the almost colourless crystals with 0 to 18.78 per cent. of the ferrous salt, and 100 to 81.22 per cent. of the magnesium salt, are rhombic; and the pale green crystals with 45.93 to 100 per cent. of the ferrous salt, and 54.07 to 0 per cent. of the magnesium salt, are monoclinic. The sp. gr. and sp. vol. of some of the solid soln., Fig. 658, were found to be:

$\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$	5.72	13.99	21.08	31.16	41.02	54.07	81.22	88.16	94.16%
Sp. gr.	1.884	1.867	1.847	1.827	1.807	1.781	1.711	1.697	1.687
Sp. vol.	0.5308	0.5356	0.5415	0.5474	0.5533	0.5613	0.5845	0.5891	0.5927

Monoclinic

Rhombic

FIG. 657.—Mutual Solubilities of Cupric and Ferrous Sulphates in Water.

FIG. 658.—Specific Volumes of Isomorphous Mixtures of Ferrous and Magnesium Sulphates.

A. Scott obtained crystals of **zinc ferrous sulphate**, $\text{ZnSO}_4 \cdot \text{FeSO}_4 \cdot \text{H}_2\text{O}$, by

adding conc. sulphuric acid to a conc. soln. of the mixed component sulphates. J. W. Retgers found that soln. of the two salts furnish isomorphous mixtures—the colourless crystals with 0 to 10·87 per cent. of heptahydrated ferrous sulphate, and 100 to 89·13 per cent. of heptahydrated zinc sulphate, are rhombic; and the colourless to pale green crystals with 25·11 to 100 per cent. of heptahydrated ferrous sulphate, and 74·89 to 0 per cent. of heptahydrated zinc sulphate, are monoclinic. The monoclinic crystals of the zinc vitriols were studied by A. Arzruni; and A. Murmann studied the crystals of the solid soln. L. Rolla and G. Ansaldi found that the equilibrium temp. of the solid soln., $\text{ZnSO}_4 \cdot n\text{FeSO}_4 \cdot 7(1+n)\text{H}_2\text{O}$, is $16\cdot4^\circ$, and that each constituent dissociated independently of the other. C. Andreatta described the *octodecahydrate* of **zinc ferrous trisulphate**, $\text{Zn}_2\text{Fe}(\text{SO}_4)_3 \cdot 18\text{H}_2\text{O}$, which occurred as a mineral in **crusts in the artificial caves** of the mines at Raibl, Trentino. The mineral was called **bianchite**—after A. Bianchi. It occurs in minute, white, microscopic needles resembling goslarite. The crystals are monoclinic. This agrees with the X-radiograms. The optical character is negative; the optical **axial** angle is small, $2V=10^\circ$. The dispersion is weak. The *dihydrate*, $\text{Zn}_2\text{Fe}(\text{SO}_4)_3 \cdot 2\text{H}_2\text{O}$, is formed at 150° , and the anhydrous salt at 260° . The crystals are soluble in water. H. Vohl, and A. Bette prepared **ammonium zinc ferrous sulphate**, $2(\text{NH}_4)_2\text{SO}_4 \cdot \text{ZnSO}_4 \cdot \text{FeSO}_4 \cdot 12\text{H}_2\text{O}$, and **potassium zinc ferrous sulphate**, $2\text{K}_2\text{SO}_4 \cdot \text{ZnSO}_4 \cdot \text{FeSO}_4 \cdot 12\text{H}_2\text{O}$, from a mixed soln. of the three constituent salts. They are probably isomorphous mixtures. D. Ostersetzer found that hexahydrated ammonium ferrous sulphate and hexahydrated ammonium zinc sulphate form solid soln. in all proportions, and that the effect of temp. is insignificant. Expressing the concentrations in grams per 100 c.c. of sat. soln., at 7° :

Soln. { Fe-salt	279·49	236·84	220·24	158·60	101·64	54·36	0
{ Zn-salt	0	18·99	22·47	46·88	70·93	92·10	125·50

Fe-salt in solid	100	85·7	76·57	49·52	29·51	13·18	0 mol. %

B. Haber-Chuwis observed similar phenomena with the hexahydrated potassium ferrous sulphate and hexahydrated potassium zinc sulphate, at $6\text{--}8^\circ$:

Soln. { Fe-salt	329·15	275·03	203·22	142·76	119·46	68·10	0
{ Zn-salt	0	19·39	47·62	63·87	67·83	77·78	113·62

Fe-salt in solid	100·00	93·55	81·98	69·45	64·29	47·22	0 mol. %

According to A. Étard, **zinc ferrous hydrosulphate**, $2\text{ZnSO}_4 \cdot 2\text{FeSO}_4 \cdot \text{H}_2\text{SO}_4$, is formed in rose-coloured crystals by adding a large excess of conc. sulphuric acid to a conc. soln. of the component salts and heating to about 200° . A. F. Walter von Escher observed that in the electrolysis of neutral and feebly acidic soln. of equimolar proportions of zinc and ferrous sulphates, at ordinary temp., zinc is precipitated almost free from iron; and that variations in the current density have very little influence on the composition of the cathode deposit. If the ferrous salt predominates, raising the temp., and decreasing the current density reduces the deposition potential of the iron, so that more iron is deposited. The iron can act as a depolarizer on the zinc deposit. At high temp. and with soln. rich in iron, the proportion of zinc deposited with the iron attains a maximum with increasing current densities. The zinc then acts as a depolarizer in the separation of iron, and the cathode potential jumps to a value corresponding with the amount of zinc deposited, and the zinc is deposited at the cathode transition point. This polarizing effect of zinc goes so far that even with a concentration ratio $\text{Fe} : \text{Zn} = 9 : 1$, and a high current density, zinc is the chief constituent of the cathode deposit as soon as the transition point is passed. The polarizing effect of the zinc in the cathode deposit on the separation of iron is aided by the charging of the cathode with hydrogen. The composition of the cathode deposit is independent of the thickness of the layer. The polarization phenomena are explained by the assumption that hypothetical intermediate products are formed during the electrolytic separation of

these metals, and that in the case of the iron group of metals these intermediate products are slowly transformed. The transformation is retarded by zinc or hydrogen. E. C. Eckel described a mineral from Colorado, $2(\text{FeSO}_4 \cdot 7\text{H}_2\text{O}) \cdot (\text{Cu}, \text{Zn})\text{SO}_4 \cdot 7\text{H}_2\text{O}$.

J. W. Retgers did not obtain **cadmium ferrous sulphate**, but rather colourless, monoclinic crystals of the trihydrate or the tritrichohydrates, $(\text{Cd}, \text{Fe})\text{SO}_4 \cdot 2\frac{2}{3}\text{H}_2\text{O}$, with 0 to 0.26 per cent. of the hydrated ferrous salt, and 100 to 99.74 per cent. of the hydrated cadmium salt; and also pale green, monoclinic crystals of the heptahydrates with 51.08 to 100 per cent. of the ferrous salt, and 48.92 to 0 per cent. of the cadmium salt. W. Stortenbeker examined the composition of soln. and crystals and found that with 100 to 79.8 molar per cent. of cadmium in soln., the crystals of $(\text{Cd}, \text{Fe})\text{SO}_4 \cdot 2\frac{2}{3}\text{H}_2\text{O}$ contained 100 to 99.1 molar per cent. of cadmium, and with 79.8 to 0 molar per cent. of cadmium in soln., the crystals of $(\text{Cd}, \text{Fe})\text{SO}_4 \cdot 7\text{H}_2\text{O}$ contained 36.6 to 0 molar per cent. of cadmium. The results are plotted in Fig. 659.

FIG. 659.—Relation between the Composition of Soln. and of Crystals of Cadmium and Ferrous Sulphates.

Yellowish or greenish-white, silky fibres or needles of a **ferrous aluminium sulphate**, $\text{FeSO}_4 \cdot \text{Al}_2(\text{SO}_4)_3 \cdot 24\text{H}_2\text{O}$, occur at Bodenmais, and Mörsfeld, in Bavaria; Uramia, in Persia; Hurlet and Campsie, near Glasgow; Björkbakkagard, in Finland; Tierra Amarilla, Chile; Iceland; Rossville, New York; Silver City, New Mexico; Tepeji, Mexico; East Greta, New South Wales, etc. Reports of analyses of the salt were made by M. H. Klaproth, J. D. Dana, A. E. Arppe, C. F. Rammelsberg, G. Forchhammer, A. Scacchi, G. Linck, E. H. S. Bailey, E. Dietrich, A. Brunner, S. Singer, V. R. von Zepharovich, F. W. Clarke, J. C. H. Mingaye, T. P. Lippitt, P. Berthier, R. Phillips, R. Brandes, etc. It was called *hversalt* by G. Forchhammer; *halotrichine* by A. Scacchi; and **halotrichite**—from *ἄλς*, salt, and *θρίξ*, hair—by E. F. Glocker. The term halotrichite was wrongly applied by J. F. L. Hausmann to alunogen. It is also called *hair-salt*, and *feather alum*. The term *mountain butter*, or *Berg-butter*, is applied to an impure efflorescence of a buttery consistency oozing from some alum slates. The crystals are monoclinic or triclinic. The crystals were examined by G. Linck, J. Uhlig, G. Cesaro, and A. Arzruni. D. Paterson found the salt as an efflorescence on bricks which had been exposed continuously to sulphur dioxide in bleaching chambers. When broken up, the mass exhibited a silky or fibrous texture like asbestos. F. Wirth, and C. Klauer prepared the salt by concentrating a soln. of equimolar proportions of the component salts. Ordinary ferrous sulphate crystallizes out first, and after that, ferrous aluminium sulphate. The crystals are washed with alcohol and ether. The salt appears white, and has a green fluorescence; it is readily soluble in water; 18 of the 24 mols. of water are expelled at 100° , and the remainder above this temp. The salt melts on warming, and decomposes forming oxides at a high temp. A. Étard prepared white, hexagonal plates of **ferrous aluminium hydrosulphate**, $2\text{FeSO}_4 \cdot \text{Al}_2(\text{SO}_4)_3 \cdot \text{H}_2\text{SO}_4$, by adding an excess of conc. sulphuric acid to a cold, conc. soln. of the component salts, and heating it to 200° . The ternary system, at 25° , was studied by V. J. Occleshaw, Fig. 660. The two salts mutually depress each other's solubility. There are three solubility curves. Hydrated aluminium sulphate, $\text{Al}_2(\text{SO}_4)_3 \cdot 18\text{H}_2\text{O}$, is the stable solid phase in contact with soln. containing less than 4.13 per cent. ferrous sulphate, FeSO_4 . At this point the soln. contains 25.4 per cent. aluminium sulphate, $\text{Al}_2(\text{SO}_4)_3$. From this point, until a liquid phase is reached containing 10.17 per cent. FeSO_4 and 20.16 per cent. $\text{Al}_2(\text{SO}_4)_3$, the stable solid in contact with the soln. is a double salt of the composition, $\text{FeSO}_4 \cdot \text{Al}_2(\text{SO}_4)_3 \cdot 24\text{H}_2\text{O}$, corresponding to the alums.

With higher concentrations of ferrous sulphate the soln. are in contact with ferrous sulphate heptahydrate, $\text{FeSO}_4 \cdot 7\text{H}_2\text{O}$, as the stable solid. There is a congruent point on the curve corresponding to the double salt. This was confirmed experimentally by crystallizing the double salt from a soln. containing ferrous sulphate

FIG. 660.—The Ternary System :
 $\text{Al}_2(\text{SO}_4)_3\text{--FeSO}_4\text{--H}_2\text{O}$, at 25° .

and aluminium sulphate in equimolecular proportions. The salt so obtained consisted of white needles which matted on the filter to an asbestos-like mass. J. Bouis observed a variety of feather salt with magnesium sulphate—**magnesium ferrous aluminium sulphate**, $\text{MgSO}_4 \cdot \text{FeSO}_4 \cdot \text{Al}_2(\text{SO}_4)_3 \cdot 15\text{H}_2\text{O}$ —occurring in the pyrites at Fort Aries. A. Scott prepared pale yellowish-green, homogeneous crystals of **ferrous chromous sulphate**, $\text{CrSO}_4 \cdot \text{FeSO}_4 \cdot 2\text{H}_2\text{O}$, from a conc. soln. of a mixture of chromous acetate, and ferrous sulphate, treated with a large excess of conc. sulphuric acid. The salt, however, may be an isomorphous mixture.

A. Etard obtained **ferrous chromic hydrosulphate**, $2\text{FeSO}_4 \cdot \text{Cr}_2(\text{SO}_4)_3 \cdot \text{H}_2\text{SO}_4 \cdot 2\text{H}_2\text{O}$, by the method employed for the corresponding aluminium salt.

G. Werther, and J. E. Willm prepared **thallous ferrous sulphate**, $\text{Tl}_2\text{SO}_4 \cdot \text{FeSO}_4 \cdot 6\text{H}_2\text{O}$, from a soln. of the component salts. The salt was also prepared by A. Benrath. The pale green, monoclinic prisms were found by G. Werther to have the axial ratios $a : b : c = 0.7366 : 1 : 0.4964$, and $\beta = 105^\circ 52'$. A. E. H. Tutton also found that the pale green crystals are monoclinic, with the axial angles $a : b : c = 0.7427 : 1 : 0.4999$, and $\beta = 106^\circ 16'$. The topic axial ratios are, $\chi : \psi : \omega = 6.2050 : 8.3547 : 4.1765$. The usual cleavage is parallel to (201). The sp. gr. is 3.650, and the mol. vol. 207.84. The optic axial angles are for the

	Li-	C-	Na-	Tl-	Cd-	F-lines
$2E'$	$129^\circ 35'$	$129^\circ 45'$	$131^\circ 35'$	$133^\circ 47'$	$135^\circ 26'$	$137^\circ 20'$
$2V_a$	$68^\circ 44'$	$68^\circ 46'$	$69^\circ 0'$	$69^\circ 26'$	$69^\circ 43'$	$69^\circ 59'$

The refractive indices are for the

	Li-	C-	Na-	Tl-	Cd-	F-	G-lines
α	1.5880	1.5886	1.5929	1.5980	1.6009	1.6040	1.6115
β	1.6041	1.6048	1.6093	1.6146	1.6175	1.6209	1.6285
γ	1.6110	1.6117	1.6162	1.6223	1.6256	1.6292	1.6370

and the general formula for the β -index is $1.5916 + 4.20091\lambda^{-2} + 71302000000000\lambda^{-4} +$ and if the constant 1.5916 be reduced by 0.0164, the formula represents the α -index, and the γ -index if it be reduced by 0.0069. The sp. refractions with μ^2 -formula are, for the C-ray, $\alpha = 0.0923$, $\beta = 0.0943$, and $\gamma = 0.0952$; and for the H_γ -ray, $\alpha = 0.0952$, $\beta = 0.0973$, and $\gamma = 0.0983$. The corresponding sp. dispersions, $\mu_G - \mu_C$, are $\alpha = 0.0029$, $\beta = 0.030$, and $\gamma = 0.0031$. The mol. refractions for the C-ray are $\alpha = 70.00$, $\beta = 71.56$, and $\gamma = 72.22$; and for the H_γ -ray, $\alpha = 72.20$, $\beta = 73.81$, and $\gamma = 74.60$; so that the mol. dispersions are $\alpha = 2.2$, $\beta = 2.25$, and $\gamma = 2.38$. The mol. refractions with the μ -formula and the C-ray are $\alpha = 122.23$, $\beta = 125.70$, and $\gamma = 127.14$ —mean 125.05. G. Werther found that the crystals do not effloresce, but the surfaces become dull. The salt loses all its water at 120° , and at a red-heat forms oxides with the loss of sulphur trioxide. The salt sinters slowly without melting when it is heated.

A. Scott prepared **manganous ferrous sulphate**, $\text{MnSO}_4 \cdot \text{FeSO}_4 \cdot 2\text{H}_2\text{O}$, in faint pink crystals, from a conc. soln. of the component salts treated with sulphuric acid in large excess. The salt may be an isomorphous mixture, because A. McL. White observed that the mutual, percentage solubility of ferrous and manganous sulphate, is :

	0°				25°				
MnSO ₄	3.07	10.66	19.18	31.84	39.39	37.83	36.95	13.57	0.09
FeSO ₄	12.55	9.26	5.69	0.14	0.33	1.33	1.82	14.39	23.09
Solid phase	Heptahydrate solid solution				Pentahydrate solid soln.	Transition point	Heptahydrate solid solution		

Observations were also made by J. W. Retgers. H. Vohl obtained **ammonium manganous ferrous sulphate**, $2(\text{NH}_4)_2\text{SO}_4 \cdot \text{MnSO}_4 \cdot \text{FeSO}_4 \cdot 12\text{H}_2\text{O}$, and also **potassium manganous ferrous sulphate**, $3\text{K}_2\text{SO}_4 \cdot \text{MnSO}_4 \cdot \text{FeSO}_4 \cdot 12\text{H}_2\text{O}$, from soln. of the three component salts. These triple salts may be isomorphous mixtures.

P. C. Ray and P. B. Sarkar⁴ prepared monoclinic crystals of a series of isomorphous salts with one member **ammonium ferrous sulphatofluoberyllate**, $(\text{NH}_4)_2\text{BeF}_4 \cdot \text{FeSO}_4 \cdot 6\text{H}_2\text{O}$, where Ni, Co, Mn, Cd, Zn, and Mg may take the place of Fe. The salt was discussed by H. Seifert.

§ 45. Ferric Sulphate

Anhydrous ferric sulphate, $\text{Fe}_2(\text{SO}_4)_3$, was analyzed by T. Thomson.¹ The salt unites with water to form a number of hydrates, some of which have been reported

as chemical individuals, but this does not give them all a *locus standi* in the list of chemical compounds. The hydrated forms are :

Dodecahydrate, $\text{Fe}_2(\text{SO}_4)_3 \cdot 12\text{H}_2\text{O}$	Ihleite.
Decahydrate, $\text{Fe}_2(\text{SO}_4)_3 \cdot 10\text{H}_2\text{O}$	Quenstedite.
Enneahydrate, $\text{Fe}_2(\text{SO}_4)_3 \cdot 9\text{H}_2\text{O}$	{ hexagonal	Coquimbite.
	{ rhombic	Janosite.
Hemipentadecahydrate, $\text{Fe}_2(\text{SO}_4)_3 \cdot 7\frac{1}{2}\text{H}_2\text{O}$	Kornelite.
Heptahydrate, $\text{Fe}_2(\text{SO}_4)_3 \cdot 7\text{H}_2\text{O}$	
Hexahydrate, $\text{Fe}_2(\text{SO}_4)_3 \cdot 6\text{H}_2\text{O}$	Lausenite.
Tetrahydrate, $\text{Fe}_2(\text{SO}_4)_3 \cdot 4\text{H}_2\text{O}$	
Trihydrate, $\text{Fe}_2(\text{SO}_4)_3 \cdot 3\text{H}_2\text{O}$	
Dihydrate, $\text{Fe}_2(\text{SO}_4)_3 \cdot 2\text{H}_2\text{O}$	

The preparation of ferric sulphate.—Anhydrous ferric sulphate was found by G. Keppeler to be formed by the action of sulphur trioxide or sulphur dioxide and oxygen on ferric oxide : $2\text{Fe}_2\text{O}_3 + 6\text{SO}_2 + 3\text{O}_2 \rightleftharpoons 2\text{Fe}_2(\text{SO}_4)_3$, or $\text{Fe}_2\text{O}_3 + 3\text{SO}_3 \rightleftharpoons \text{Fe}_2(\text{SO}_4)_3$. The reaction is not perceptible at 200° , it begins about 230° , and is very marked at 450° ; it is retarded if moisture be present. The reaction was studied by G. Keppeler and J. d'Ans, G. Lunge and L. Pollit, F. Wöhler and co-workers, and B. Neumann and E. Goebel—*vide* sulphur trioxide, 10. 57, 337. As indicated in connection with ferrous sulphate, some ferric sulphate is formed during the weathering of iron pyrites. C. Dittler, for instance, observed that it is formed when oxygen acts on a slurry of ground marcasite. G. Keppeler reported the sulphate to be formed as an intermediate stage in the action of sodium chloride on pyrite at an elevated temp. : $2\text{FeS}_2 + 2\text{NaCl} + 8\text{O}_2 = \text{Fe}_2(\text{SO}_4)_3 + \text{Na}_2\text{SO}_4 + \text{Cl}_2$; R. Saxon also observed ferric sulphate to be formed during the electrolysis of sulphuric acid using iron pyrite as cathode. J. d'Ans, and B. Neumann represented the action of heat on ferrous sulphate whilst air is excluded, $6\text{FeSO}_4 \rightleftharpoons \text{Fe}_2(\text{SO}_4)_3 + 2\text{Fe}_2\text{O}_3 + 3\text{SO}_2$; F. Warlimont represented the action of oxygen : $6\text{FeSO}_4 + 3\text{O} \rightleftharpoons 2\text{Fe}_2(\text{SO}_4)_3 + \text{Fe}_2\text{O}_3$; and G. Keppeler and J. d'Ans, the action of sulphur trioxide : $2\text{FeSO}_4 + 2\text{SO}_3 = \text{SO}_2 + \text{Fe}_2(\text{SO}_4)_3$ —this reaction occurs only at a low temp., because at a high temp. the product is dependent on the composition of the gas-phase. A. Recoura observed that if hydrated ferric sulphate be heated to 175° it produces a yellow modification of the anhydrous salt; and similarly also when the acid ferric sulphates are heated. R. Scharizer observed that monohydrated ferric sulphate is formed at 128° , and the anhydrous salt at 135° ; F. Wirth and B. Bakke recommended 175° for the anhydrous salt; and H. Saito found that the enneahydrate is completely dehydrated in air at 250° —Fig. 669—and at 230° in air with 5 per cent. of sulphur dioxide. M. Lachaud and C. Lepière also prepared the anhydrous salt by the thermal decomposition of ammonium ferric sulphate, or by heating ferrous ammonium sulphate repeatedly in the presence of ammonium sulphate.

According to A. Vesterberg, J. Loczka, P. Hart, F. Ulrich, V. von Lang, and A. W. Davidson, if hydrated ferric sulphate be treated with conc. sulphuric acid, anhydrous ferric sulphate is formed as the solid phase; and E. Posnjak and H. E. Merwin observed that the anhydrous salt appears as the solid phase at 140° when the percentage proportions of Fe_2O_3 : SO_3 : H_2O , are 0.08 to 0.64 : 74.95 to 53.51 : 24.97 to 46.05; and at 200° , when these proportions are 0.04 to 1.5; 76.17 to 50.5 : 23.79 to 48.0—cf. Figs. 661 to 668.

The preparation of the hydrates of ferric sulphate.—A. Vesterberg prepared a soln. of ferric sulphate by dissolving *ferrum reductum* in hot sulphuric acid (1 : 1), evaporating the soln., and keeping it boiling for a couple of days until a reddish crystalline powder of anhydrous ferric sulphate is formed. Anhydrous ferric sulphate was also prepared by P. Hart, G. Fownes, W. B. Giles, E. Divers and T. Shimidzu by dissolving powdered heptahydrated ferrous sulphate in boiling conc. sulphuric acid : $2\text{FeSO}_4 + \text{H}_2\text{SO}_4 = \text{Fe}_2(\text{SO}_4)_3 + \text{H}_2$. J. Milbauer and O. Quadrant recommended boiling 10 grms. of heptahydrated ferrous sulphate with 100 c.c.

of conc. sulphuric acid for about an hour; the bulk of the acid is then to be poured away, and the residue washed with alcohol, and finally with dry ether. The salt is then to be dried to constant weight. J. Loczka said that ferrous sulphide, marcasite, or pyrite can be similarly treated with conc. sulphuric acid. G. T. Gerlach, and S. U. Pickering commented on the difficulty in removing the excess of sulphuric acid from the product, and recommended heating the product until it assumes a light brown colour when hot, and has a pink colour when cold—the coloration is attributed to the presence of some ferric oxide. To remove the excess of acid from the ferric sulphate, C. R. C. Tichborne recommended heating the product for some days at 75°; A. Recoura recommended 120° to 150°; and G. Keppeler and J. d'Ans, M. Bodenstein and T. Suzuki, and E. Kothny, 400° to 450°.

L. J. Thénard, K. Seubert and R. Rohrer, F. K. Cameron and W. O. Robinson, and C. P. Prückner obtained a soln. of ferric sulphate by dissolving ferric oxide, or hydrated ferric oxide, or basic ferric sulphate in sulphuric acid. R. C. Wells obtained a soln. of ferric sulphate with the ratios $\text{Fe}_2\text{O}_3 : \text{SO}_3 = 1 : 3$, by dissolving freshly-precipitated hydrated ferric oxide in a soln. of ordinary ferric sulphate, and then adding the calculated quantity of sulphuric acid. When an aq. soln. of ferrous sulphate is exposed to air, or boiled with a suitable oxidizing agent, freed from the oxidizing agent by boiling or by repeated solution and evaporation to dryness, ferric sulphate is formed. This method was employed by C. F. Bucholz, C. R. C. Tichborne, M. Berthelot, and G. Keppeler and J. d'Ans. A. Recoura recommended removing the nitric acid by heating the dried product some days at 120°, and then at 140°. L. W. Pissarjewsky employed hydrogen dioxide as oxidizing agent in place of nitric acid.

F. Ulrich found crystals of ferric sulphate accidentally formed in a platinum dish used for concentrating sulphuric acid. A. and P. Buisine obtained ferric sulphate by the action of sulphuric acid of sp. gr. 1.53 to 1.82, on roasted pyrites. C. Dreyfus obtained ferric sulphate from waste sulphuric acid and waste iron residues; E. Hermite and A. Dubosc, by the electrolysis of a soln. of ferrous sulphate to which a dil. soln. of ferrous, sodium, potassium, calcium, vanadium, or magnesium chloride had been added.

As indicated below, the aq. soln. of ferric sulphate is readily hydrolyzed, and, as is so frequently the case with salts prone to hydrolysis, chemists in the past have recorded a list of basic salts, and nature too has here played her part, so that many of the basic salts have been recorded as special minerals. So far as chemical analyses can tell, there might be an indefinitely large number of products when there is no break in the continuity of the process of transformation, by hydrolysis, from pure ferric sulphate to pure ferric hydroxide. S. U. Pickering, and F. K. Cameron and W. O. Robinson would make a drastic sweep of the numerous basic salts which have been obtained artificially or reported as minerals, from the list of chemical individuals, by denying their existence as chemical compounds. F. K. Cameron and W. O. Robinson regard them all as either mixtures or solid soln. whose composition depends on arbitrary conditions of concentration, temperature, or pressure. S. U. Pickering maintained that only one basic salt exists as a chemical individual, namely $\text{Fe}_2(\text{SO}_4)_3 \cdot 5\text{Fe}_2\text{O}_3$. Many of the synthesized products, formed by precipitation, hydrolysis, or fractional evaporation, were obtained under conditions where equilibrium could not have been attained, so that mixtures were produced. The slowness at which the products react with water gave the impression that definite, stable compounds were formed. The stability was only apparent, not real. F. K. Cameron and W. O. Robinson were guided in their work by the phase rule, and from their study of the system $\text{Fe}_2\text{O}_3\text{--SO}_3\text{--H}_2\text{O}$, at 25°, they inferred: (i) no definite basic sulphates are formed at this temp., but a stable solid phase with up to about 25 per cent. of H_2SO_4 is one of a series of solid soln. involving these three constituents; (ii) decahydrated normal ferric sulphate is the stable solid phase with soln. containing 25 to 28 per cent. of sulphuric acid; and (iii) the stable solid phase with soln. containing 28 per cent. of sulphuric acid has the

composition: $\text{Fe}_2\text{O}_3 \cdot 4\text{SO}_3 \cdot 10\text{H}_2\text{O}$. These conclusions have not been confirmed by subsequent workers.

F. Wirth and B. Bakke studied the system $\text{Fe}_2\text{O}_3\text{--SO}_3\text{--H}_2\text{O}$ at 25° . They were unable to establish the existence of definite solid phases in equilibrium with soln. containing less than 26 per cent. of SO_3 , but they confirmed the existence of the basic salt $2\text{FeO}_3 \cdot 5\text{SO}_3 \cdot 17\text{H}_2\text{O}$ occurring in two forms corresponding with the mineral α - and β -copiapite; they also found crystals of enneahydrated ferric sulphate, and of the acid salt $\text{Fe}_2\text{O}_3 \cdot 4\text{SO}_3 \cdot 9\text{H}_2\text{O}$. M. P. Applebey and S. H. Wilkes obtained the results, summarized in Figs. 661 and 662, at 25° , when the concentrations are expressed in grams per 100 grms. of sat. soln.:

Fe_2O_3	0.27	3.88	8.04	13.80	17.52	18.56	19.98	7.91
SO_3	39.77	33.20	13.80	30.02	29.85	29.98	29.19	9.18
	$\text{Fe}_2\text{O}_3 \cdot 4\text{SO}_3 \cdot 9\text{H}_2\text{O}$		$\text{Fe}_2\text{O}_3 \cdot 3\text{SO}_3 \cdot 7\text{H}_2\text{O}$		$7\text{Fe}_2\text{O}_3 \cdot 15\text{SO}_3$		Solid solution	

FIG. 661.—Equilibrium in the System: $\text{Fe}_2\text{O}_3\text{--SO}_3\text{--H}_2\text{O}$, at 18° .

FIG. 662.—Equilibrium in the System: $\text{Fe}_2\text{O}_3\text{--SO}_3\text{--H}_2\text{O}$, at 25° .

The basic salt $7\text{Fe}_2\text{O}_3 \cdot 15\text{SO}_3$ does not appear in the system at 18° . According to E. Posnjak and H. E. Merwin, in these experiments allowance was not always made for the fact, reported by A. Maus, that (i) soln. of ferric sulphate dissolve precipitated ferric oxide; (ii) ferric oxide adsorbs ferric sulphate from its soln.; and (iii) equilibria are obtained with great sluggishness in viscid soln. The following is a selection of the results of E. Posnjak and H. E. Merwin at 200° where concentrations are represented in grams per 100 grms. of sat. soln.:

Fe_2O_3	0.56	0.63	1.69	3.50	2.00	1.91	1.35	0.04
SO_3	4.90	5.58	11.39	19.43	41.87	48.94	52.12	76.17
	Fe_2O_3		$\text{Fe}_2\text{O}_3 \cdot 2\text{SO}_3 \cdot \text{H}_2\text{O}$				$\text{Fe}_2\text{O}_3 \cdot 3\text{SO}_3$	

and they are plotted in Fig. 663. The results at 140° were:

FIG. 663.—Equilibrium in the System: $\text{Fe}_2\text{O}_3\text{--SO}_3\text{--H}_2\text{O}$, at 200° .

FIG. 664.—Equilibrium in the System: $\text{Fe}_2\text{O}_3\text{--SO}_3\text{--H}_2\text{O}$, at 140° .

Fe_2O_3	0.01	0.05	1.18	9.84	12.05	15.35	3.71	0.64	0.08
SO_3	0.82	2.60	4.06	17.65	22.39	30.88	37.10	53.31	74.95
	Fe_2O_3		$3\text{Fe}_2\text{O}_3 \cdot 4\text{SO}_3 \cdot 9\text{H}_2\text{O}$		$\text{Fe}_2\text{O}_3 \cdot 2\text{SO}_3 \cdot \text{H}_2\text{O}$		$\text{Fe}_2\text{O}_3 \cdot 3\text{SO}_3 \cdot 6\text{H}_2\text{O}$		$\text{Fe}_2\text{O}_3 \cdot 3\text{SO}_3$

and they are plotted in Fig. 664. The results at 110° are :

Fe_2O_3	0.01	0.08	14.51	19.74	19.04	1.26	0.81	0.48	0.15	0.06

	$\text{Fe}_2\text{O}_3 \cdot \text{H}_2\text{O}$		$3\text{Fe}_2\text{O}_3 \cdot 4\text{SO}_3 \cdot 9\text{H}_2\text{O}$		$\text{Fe}_2\text{O}_3 \cdot 2\text{SO}_3 \cdot \text{H}_2\text{O}$		$\text{Fe}_2\text{O}_3 \cdot 3\text{SO}_3 \cdot 6\text{H}_2\text{O}$		$\text{Fe}_2\text{O}_3 \cdot 4\text{SO}_3 \cdot 3\text{H}_2\text{O}$		

All these results are represented as an equilibrium surface in Fig. 668. G. Tunell

and E. Posnjak studied the effect of copper sulphate on a portion of the system—*vide infra*.

A. Schrauf reported a *dodecahydrate*, $\text{Fe}_2(\text{SO}_4)_3 \cdot 12\text{H}_2\text{O}$, to occur in the graphite deposits of Mugrau, Bohemia; and he named it *ihleite*—after M. Ihle. Specimens were found elsewhere by R. von Görgy, and F. Slavik; and analyses were made by B. Erben, and A. Schrauf. R. Scharizer doubted the individuality of *ihleite*; he regarded it as a mixture of *copiapite* and *rhomboclase*; and E. Manasse considered it to be impure *copiapite*. No evidence of the *dodecahydrate* has been obtained in the equilibrium studied in the system Fe_2O_3 – SO_3 – H_2O at different temp.; and a similar remark applies to the *decahydrate*, $\text{Fe}_2(\text{SO}_4)_3 \cdot 10\text{H}_2\text{O}$, reported by G. A. Bertels, and A. C. Oudemans to separate from the soln. obtained by the action of nitric and sulphuric acids on ferrous sulphate. F. K. Cameron and W. O. Robinson said that the *decahydrate* is formed by the action of water or moisture on the anhydrous salt, and by shaking of a soln. of ferric sulphate with freshly-precipitated ferric hydroxide in soln. containing 25 to 28 per cent. of SO_3 at 25° . E. Posnjak and H. E. Merwin do not consider the evidence satisfactory. G. Linck reported the mineral *quenstedtite*—named after F. A. Quenstedt—to be the *decahydrate* occurring with *coquimbite* and other sulphates at Tierra Amarilla, Copiapo, Chili.

In 1833, H. Rose reported the occurrence at Tierra Amarilla, Copiapo, Chili, of an *enneahydrate*, $\text{Fe}_2(\text{SO}_4)_3 \cdot 9\text{H}_2\text{O}$. This was confirmed by the analyses of G. Linck, H. F. Collins, J. B. Macintosh, C. Lausen, R. Scharizer, L. Darapsky, and R. Serrano. J. D. Dana, and C. Lausen gave $2(\text{Fe}, \text{Al})_2\text{O}_3 \cdot 7\text{SO}_3 \cdot 22\text{H}_2\text{O}$. J. D. Dana called the mineral *blakeite*—after W. P. Blake—but A. Breithaupt's earlier name *coquimbite* is generally employed, even though the mineral does not occur at Coquimbo, Chili. R. Scharizer said that the *enneahydrate* is obtained in hexagonal plates by evaporating to dryness a soln. of hydrated ferric oxide in an excess of sulphuric acid, and washing the product with alcohol. F. Wirth and B. Bakke observed that *coquimbite* is stable at ordinary temp. in soln. containing 31.54 to 27.98 per cent. of SO_3 , 9.39 to 16.07 per cent. of Fe_2O_3 , and 59.07 to 55.93 per cent. of water; M. P. Applebey and S. H. Wilkes, in soln. with 31.88 to 29.72 per cent. SO_3 , 9.63 to 17.48 per cent. of Fe_2O_3 , and 58.49 to 52.79 per cent. of H_2O ; and R. Scharizer said that this hydrate is the stable phase when the mol. quotient $\text{SO}_3 : \text{Fe}_2\text{O}_3$ is greater than 3 and less than 4. H. Böckh described a rhombic form of the *enneahydrate*—*coquimbite* is hexagonal. The rhombic *enneahydrate* was called *janosite*, and it was obtained from Vashegy, Hungary. E. Weinschenk, E. Wülfing, W. H. Melville and W. Lindgren, Z. Toborffy, and R. Scharizer considered *janosite* to be impure *copiapite*. The sulphate from Leona Heights, California, described by W. T. Schaller, is probably a related mineral. According to A. Recoura, when a conc. soln. of ferrous sulphate is exposed to air for several days, it deposits a spongy, nodular, saffron-yellow mass consisting of the basic sulphate, $6\text{Fe}_2(\text{SO}_4)_3 \cdot \text{Fe}_2\text{O}_3 \cdot \text{H}_2\text{O}$, impregnated with an acid sulphate of variable constitution which can be removed by extraction with absolute alcohol. When a specimen of the yellow mass having the composition $\text{Fe}_2(\text{SO}_4)_3 \cdot 11\text{H}_2\text{O}$, was treated with alcohol, 89 per cent. of the iron remained in the form of the basic sulphate. If the yellow mass is allowed to dry in air until it has reached the composition $\text{Fe}_2(\text{SO}_4)_3 \cdot 9\text{H}_2\text{O}$, the basic and acid sulphates recombine, and can no longer be separated by alcohol. The solidification of ferric sulphate on evaporation of its soln. takes place therefore in two stages. In consequence of this, the yellow mass is not homogeneous, but contains in some parts an excess of the basic, in others of the acid salt. If this is made into a paste with a little water and spread on a plate, at the end of 24 hrs. the ferric sulphate, $\text{Fe}_2(\text{SO}_4)_3 \cdot 9\text{H}_2\text{O}$, is obtained as a white, homogeneous layer. The ordinary form is yellow. A. Recoura added that the white and yellow hydrated ferric sulphates must differ in constitution. The yellow sulphate dissolves immediately in water, but the white modification does so only slowly. Whilst both sulphates are soluble in absolute alcohol without decomposition, the yellow modifi-

cation is decomposed to the insoluble basic sulphate and the soluble acid sulphate, $\text{Fe}_2\text{O}_3 \cdot 4\text{SO}_3$, on treatment with 95 per cent. alcohol, or with a little water, or on exposure to moist air, under which conditions the white modification is stable.

J. A. Krenner reported a rose-red or violet *hemipentadecahydrate*, $\text{Fe}_2(\text{SO}_4)_3 \cdot 7\frac{1}{2}\text{H}_2\text{O}$, to occur at Szomobnok, Hungary, and he called it **kornelite**—after Kornel Hlavacek. It was analyzed by J. Loczka; and it is considered to have been the heptahydrate. According to F. Wirth and B. Bakke, the enneahydrate is the normal salt stable at 25° , but M. P. Applebey and S. H. Wilkes found that in presence of sulphuric acid, the normal salt at 18° to 25° is the *heptahydrate*, $\text{Fe}_2(\text{SO}_4)_3 \cdot 7\text{H}_2\text{O}$. E. Posnjak and H. E. Merwin observed that the heptahydrate is stable in contact with its sat. soln. of sulphuric acid below 80° . Taking percentage proportions of the three constituents $\text{Fe}_2\text{O}_3 : \text{SO}_3 : \text{H}_2\text{O}$, E. Posnjak and H. E. Merwin showed that the stable phase, Figs. 666 and 667, is the heptahydrate, at 75° , when $\text{Fe}_2\text{O}_3 : \text{SO}_3 : \text{H}_2\text{O}$ is 18.13 to 19.0 : 32.32 : 49.55 to 48.8, and at 50° , 7.5 to 16.78 : 33.0 to 30.72 : 59.5 to 52.5. M. P. Applebey and S. H. Wilkes, at 25° , gave 8.04 to 13.80 : 32.06 to 30.02 : 59.90 to 56.18, and at 18° , 9.63 to 18.68 : 31.88 to 29.64 : 58.49 to 51.68. E. Posnjak and H. E. Merwin said that whilst the heptahydrate is the stable phase between 25° and 50° under the conditions first indicated, the stable phase between 50° and 150° is the *hexahydrate*, $\text{Fe}_2(\text{SO}_4)_3 \cdot 6\text{H}_2\text{O}$. Taking percentage proportions of $\text{Fe}_2\text{O}_3 : \text{SO}_3 : \text{H}_2\text{O}$, the hexahydrate appears at 140° when 0.64 to 15.5 : 53.31 to 31.5 : 46.05 to 53.0, at 110° when 1.0 to 20.0 : 43.0 to 31.0 : 56.0 to 49.0, and at 75° when 4.59 to 18.13 : 35.51 to 32.32 : 59.90 to 49.55. C. Lausen reported the hexahydrate to occur in monoclinic fibres in a mine in Arizona, and added that it was formed through the burning of some pyritic ores. It was named *rogersite*—after A. F. Rogers—but G. M. Butler said that since the name rogersite is used for another mineral, it would be more appropriate to call it **lausenite**—after C. Lausen.

According to A. Recoura, if the white enneahydrate be kept for some time at a temp. a little below 100° , it furnishes the *trihydrate*, $\text{Fe}_2(\text{SO}_4)_3 \cdot 3\text{H}_2\text{O}$, and at 175° it forms a brownish-yellow anhydrous salt, which dissolves in water very much more rapidly than that obtained by dehydrating the yellow enneahydrate. The brownish-yellow, anhydrous salt furnishes the trihydrate when exposed to moist air. R. Scharizer found that the enneahydrate coquimbite loses no water when confined over conc. sulphuric acid, but at 83° water begins to be evolved so that at 93° , 5 mols. are given off, and a *tetrahya*te, $\text{Fe}_2(\text{SO}_4)_3 \cdot 4\text{H}_2\text{O}$, remains; at 113° more water is evolved so that at about 161° , the *dihydrate*, $\text{Fe}_2(\text{SO}_4)_3 \cdot 2\text{H}_2\text{O}$, remains. Above 161° the hydrate slowly passes into the anhydrous salt. The dehydration curve, Fig. 669, shows three breaks respectively at 83° , 93° , and 161° .

FIG. 669.—The Dehydration Curve of Coquimbite, $\text{Fe}_2(\text{SO}_4)_3 \cdot 9\text{H}_2\text{O}$.

The physical properties of ferric sulphate.—The colour of anhydrous ferric sulphate has been called white, grey, pale yellow, and rose. Actually, the colour depends on the degree of purity, the temp., and the grain-size. According to S. U. Pickering, the powder is pale brown when hot and rose-red when cold. The coloration here is no doubt due to the presence of ferric oxide, since G. Keppeler and J. d'Ans found that at ordinary temp., the salt is white by reflected light, and pale bluish-green by transmitted light; whilst E. Posnjak and H. E. Merwin said that the colour is yellowish-grey when the grain-size exceeds 0.1 mm. According to A. Laurent, and A. Recoura, there are two **allotropic forms** of the anhydrous salt, one hexagonal and one rhombic. The former is white, the latter is yellow; and the former dissolves in water more slowly than the latter. F. Wirth and B. Bakke, however, showed that the alleged differences are simply effects of differences in the grain-size of the alleged forms, but his products may have been the same but in different states of subdivision. E. Posnjak and H. E. Merwin found that in their study of the ternary system, the anhydrous ferric sulphate usually appeared

in two different crystalline forms, both together. The **crystals** of both forms retained their optical properties when heated dry up to the temp. at which sulphur trioxide began to be evolved, so that their relative stability relations are unknown. Both forms hydrate slowly on exposure to air. The one form appears as flattened rhombs, greyish-yellow in colour, with the narrow prism faces over all the lateral edges, and having rhombohedral cleavage. The axial ratio of the rhombohedral crystals is $a : c = 1 : 1.35$, and the indices of refraction are $\omega = 1.770$ and $\epsilon = 1.760$. The other form has a similar colour, and appears in thick tabular crystals flattened parallel to the base. The crystals belong to the rhombic system, and have the axial ratios $a : b : c = 0.957 : 1 : 1.357$; R. Scharizer gave $0.9857 : 1 : 1.3991$; and V. von Lang reported some crystals with the vertical axis about half this length, for he gave $a : b : c = 1.0855 : 1 : 0.6715$. E. Posnjak and H. E. Merwin found the optic axial angle $2V = 60^\circ$ nearly. G. M. Smith represented the white salt, which dissolves slowly, by the formula $\text{Fe}[\text{Fe}(\text{SO}_4)_3]$ or $\text{Fe}[\text{Fe}(\text{SO}_4)_2]_3$.

G. Linck reported that quenstedtite, the decahydrate, occurs in reddish-violet, tabular crystals parallel to (010), in elongated crystals parallel to (100) like gypsum, and in crystals with the clino dome faces striated parallel to (100). The monoclinic crystals have the axial ratios $a : b : c = 0.39397 : 1 : 0.40584$, and $\beta = 78^\circ 7\frac{1}{2}'$. The (010)-cleavage is perfect; and the (100)-cleavage is less well-defined and it yields a fibrous fracture. The optical character is negative. Coquimbite, the enneahydrate, sometimes occurs in colourless, white, yellowish-, greenish-, or brownish-white, or lavender-tinted crystals which sometimes have a tinge of violet or amethyst-blue; it may also occur granular and massive; or more commonly in hexagonal prisms, or in rhombohedral forms which sometimes simulate octahedra. H. Ungemach observed that the triclinic mineral has the axial ratios $a : b : c = 0.2621 : 1 : 0.2776$, and $\alpha = 94^\circ 10'$, $\beta = 101^\circ 44.5'$, and $\gamma = 96^\circ 18.5'$. G. Linck found that the rhombohedral crystals have the axial ratio $a : c = 1 : 1.5613$, and $\alpha = 80^\circ 6'$. Twinning may occur about the (0001)-plane; the (1120)-faces may coincide and show a reversed striation parallel to the edge (3032)/(1120). The prismatic cleavage is perfect, the (1010)-, (1011)-, and the (0111)-cleavages are imperfect. The optical character is positive. The corrosion figures are equilateral triangles corresponding with the rhombohedral symmetry. The voluminous, yellow mass which A. Recoura obtained by evaporating a conc. soln. of ferric sulphate was considered to be an allotropic form of the enneahydrate; the same modification was obtained by exposing the anhydrous sulphate to moist air. The yellow form is said to dissolve in much water more readily than the white salt. R. Scharizer inferred that the yellow form is really a mixture of a basic sulphate, copiapite, and an acid sulphate; F. Wirth and B. Bakke considered the yellow form to be copiapite mixed with some acid salt; and F. K. Cameron and W. O. Robinson supposed that the yellow and white forms are chemically the same, but in different degrees of purity, and state of subdivision. E. Posnjak and H. E. Merwin said that the coarse-grained powder of the heptahydrate is rose-pink, but larger crystals are colourless, monoclinic plates. The laths are elongated to (001), and flattened parallel to (010), and there are traces of polysynthetic twinning on (010), parallel to the elongation. The hexahydrate crystallizes readily, and it is stable in contact with salt. soln. from 50° to about 150° . The slender, colourless laths are elongated parallel to (001), and flattened parallel to (010). The crystals of the hexahydrate are monoclinic. H. Ungemach gave for coquimbite the hexagonal axial ratio $a : c = 1 : 1.5643$, and for the rhombohedral variety, **paracoquimbite**, $a : c = 1 : 2.3464$.

The **specific gravity** of anhydrous ferric sulphate was found by L. F. Nilson and O. Pettersson to be 3.097 at 18.2° ; M. Lachaud and C. Lepière gave 3.05 at 14° ; and G. Keppeler and J. d'Ans, 2.937. A. Schrauf gave 1.812 for the sp. gr. of the dodecahydrate, ihleite; and G. Linck, 2.116 for the sp. gr. of the decahydrate, quenstedtite at 16.2° . A. Breithaupt gave 2.092 for the sp. gr. of the enneahydrate, coquimbite, G. Linck, 2.105; C. Lausen, 2.092; and J. D. Dana, 2.0

to 2.1. B. Franz found the sp. gr. of aq. soln. of ferric sulphate at 17.5° to be :

$\text{Fe}_2(\text{SO}_4)_3$	5	10	15	20	30	40	50	60 per cent.
Sp. gr..	1.0426	1.0854	1.1324	1.1826	1.3090	1.4506	1.6148	1.8002

Results by G. T. Gerlach, and H. Hager were a little larger than the values found by B. Franz; thus, H. Hager gave for soln. with 10, 30, and 50 per cent. of $\text{Fe}_2(\text{SO}_4)_3$, the respective values 1.097, 1.337, and 1.650. B. Cabrera and E. Moles gave :

$\text{Fe}_2(\text{SO}_4)_3$	0.351	1.173	2.963	3.978	6.678	7.986	11.259	15.382 per cent.
Sp. gr.	1.0013	1.0080	1.0237	1.0340	1.0612	1.0730	1.1132	1.1525

Observations were also made by G. Lunge and E. Berl, W. Manchot and co-workers, S. U. Pickering, and A. Heydweiller. P. F. Gaehr represented the relation between the sp. gr., D , and the percentage composition, C , by the relation: $\log_{10} D = aC$, where a is a constant. The **molecular volume** of the anhydrous salt, given by L. F. Nilson and O. Pettersson, is 129.16. G. Beck studied the subject. H. H. Stephenson discussed the contraction which occurs in the formation of the compound from its elements. G. T. Gerlach, and H. Hager calculated the change in vol. which occurs when ferric sulphate is dissolved in water. I. Traube discussed the mol. solution volume, and found that for soln. with 10, 30, and 50 per cent. $\text{Fe}_2(\text{SO}_4)_3$, the mol. soln. vol. are respectively 49.7, 68.4, and 84.9.

The **hardness** of quenstedtite is 2.5 on Mohs' scale, and that of coquimbite, 2.0 to 2.5. T. Redwood studied the **diffusion** of soln. of the salt through membranes; M. Torre found that for a soln. with 0.666 gm. of $\text{Fe}_2(\text{SO}_4)_3$ per 100 c.c., at 30°, 40°, and 50°, the changes in concentration against water, in 24 hrs., were respectively 0.240, 0.256, and 0.268 gm. per 100 c.c.; and with a soln. with 0.133 gm. $\text{Fe}_2(\text{SO}_4)_3$ per 100 c.c., respectively 0.044, 0.052, and 0.055. Z. H. Skraup discussed the **capillary rise** of soln. of ferric sulphate in filter-paper.

C. Montemartini and L. Losana found that the **thermal expansion** of a 30 per cent. soln. of ferric sulphate between 10° and 98°, on an arbitrary scale, exhibited a reversible break. L. F. Nilson and O. Pettersson found the **specific heat** of the anhydrous sulphate to be 0.1656 between 0° and 100°. F. M. Raoult observed the **lowering of the freezing-point** of a soln. of a gram of $\text{Fe}_2(\text{SO}_4)_3$ in 100 c.c. of water to be 0.115°. A. Recoura made observations on the subject. R. Scharizer's observations on the **thermal decomposition** or dehydration of crystals of the enneahydrate are summarized in Fig. 669. F. Wirth and B. Bakke said that at 98°, the enneahydrate loses 5 mols. of water; in 8 hrs. at 125°, 8 mols.; and at 175° all the water is expelled; and A. Recoura found that 6 mols. are given off at 100°, and the remaining 3 mols. at 175°. J. d'Ans, and L. and P. Wöhler and W. Plüddemann said that at temp. exceeding 200°, in the absence of air, the reaction $\text{Fe}_2(\text{SO}_4)_3 \rightleftharpoons \text{Fe}_2\text{O}_3 + 3\text{SO}_3$ occurs, and no basic sulphate or solid soln. of oxide in sulphate is formed. J. A. Hedvall and J. Heuberger found that in a current of nitrogen, the decomposition is perceptible at 660°. If a limited supply of air is available, H. O. Hofman and W. Wanjukoff found that the decomposition is complete at 530°; and K. Friedrich, and K. Friedrich and A. Bickle said 705°. K. Honda and T. Ishiwara found that ferric oxide begins to be formed at 660°. H. Saito observed that in a current of air, decomposition begins at 550°, and in a current of air with 5 per cent. of sulphur dioxide, at 620°. When the salt is heated in a closed vessel, under suitable conditions, a state of equilibrium is established. G. Keppeler found that the press. of the sulphur trioxide is imperceptible at 400°, but it is measurable at 500°. G. Keppeler and co-workers found that between 500° and 700°, the relation between the **dissociation pressure**, p mm., and the temp., $T^\circ \text{K}$., can be represented by $\log p = 11.8626 - 44720/4.584T$. In the gaseous phase there is another state of equilibrium: $2\text{SO}_3 \rightleftharpoons 2\text{SO}_2 + \text{O}_2$. They also found that the press. over the basic salt, $\text{Fe}_2\text{O}(\text{SO}_4)_2$, is less than is the case with the normal

sulphate at the same temp. L. and P. Wöhler and W. Plüddemann observed for the pressure $p = p_{\text{SO}_3} + p_{\text{SO}_2} + p_{\text{O}_2}$ mm. :

	553°	592°	634°	660°	690°	699°	707°
p	23	45	113	182	401	560	715

and for the press. of the sulphur trioxide :

	580°	600°	620°	640°	660°	680°	700°
p_{SO_3}	24.7	36.6	50.5	70.6	93.5	133.5	233.0

Measurements were also reported by L. Wöhler and M. Grünzweig, G. Marchal, P. Grünzweig, F. Warlimont, W. Plüddemann, M. Bodenstein and T. Suzuki, and W. Reinders and F. Goudriaan. The results of L. and P. Wöhler and W. Plüddemann are summarized by the continuous curve, Fig. 670, and those of G. Keppeler and J. d'Ans, by the dotted curve, Fig. 670. Unlike G. Keppeler and J. d'Ans, L. and P. Wöhler and W. Plüddemann observed that with the basic sulphate, $\text{Fe}_2\text{O}_2(\text{SO}_4)$, the dissociation press. at three different temp. were the same as those obtained with the normal sulphate. This was taken to mean that basic sulphates are not formed in the thermal dissociation of ferric sulphate, and that there is no evidence of the formation of a solid soln. of oxide and sulphate. M. Bodenstein and T. Suzuki attributed the low results obtained by G. Keppeler and J. d'Ans to an insufficient allowance of time for equilibrium to be established; they also said that if ferric sulphate dissociates into ferric oxide and sulphur trioxide, an excess of trioxide instead of a deficit would be anticipated—a deficit was observed, meaning that the mechanism of the reaction is more complex than is represented by the equation: $\text{Fe}_2(\text{SO}_4)_3 \rightleftharpoons \text{Fe}_2\text{O}_3 + 3\text{SO}_3$. F. G. Jackson studied the thermal decomposition of ferric sulphate; and K. Flick, and H. H. Willard and R. D. Fowler, the separation of a mixture of sulphates by fractional thermal decomposition.

P. A. Favre and J. T. Silbermann made some observations on the **heat of formation** of ferric sulphate; J. A. Hedvall and J. Heuberger gave for the solid salt $(2\text{Fe}, 3\text{S}, 12\text{O}) = 640$ Cals.; J. Thomsen, $(\text{Fe}_2\text{O}_3, 3\text{SO}_3) = 141.237$ Cals.; L. and P. Wöhler and W. Plüddemann gave 27.31 Cals. for the **heat of dissociation** of a mol of SO_3 from a mol of $\text{Fe}_2(\text{SO}_4)_3$ between 620° and 640°, but G. Keppeler and J. d'Ans obtained a smaller value. Calculations were also made by P. P. Budnikoff. For the heat of formation of the salt in soln., G. Keppeler and J. d'Ans gave $(2\text{Fe}, 3\text{S}, 12\text{O}, \text{Aq.}) = 659.5$ Cals.; M. Berthelot, $(2\text{Fe}, 3\text{O}, 3\text{SO}_3, \text{Aq.}) = 224.9$ Cals.; and J. Thomsen, $(2\text{FeSO}_4\text{Aq.}, \text{O}, \text{SO}_3\text{Aq.}) = 38.5$ Cals. For the **heat of neutralization**, M. Berthelot gave $(2\text{Fe}(\text{OH})_3, 3\text{H}_2\text{SO}_4\text{Aq.}) = 34.1$ Cals.; and J. Thomsen, 33.84 Cals. For the **heat of dilution** of a soln. of a mol of $\text{Fe}_2(\text{SO}_4)_3$ in 0.67 litre of water with 1.33 litres, G. Lemoine gave 4.8 Cals.; and for a soln. of a mol of $\text{Fe}_2(\text{SO}_4)_3$ in 2 litres of water with 2 and 6 litres of water, respectively 0.4 and 0.6 Cals. M. Berthelot gave for the dilution of a soln. of a mol of $\text{Fe}_2(\text{SO}_4)_3$ in 2 litres, with 6 litres, 0.6 Cals.; and for the admixture of 12 litres of a soln. of a mol of $\text{Fe}_2(\text{SO}_4)_3$ with 3 mols of H_2SO_4 (a mol per 4 litres), 2.8 Cals. G. Beck made observations on the **free energy** of the salt.

E. Posnjak and H. E. Merwin measured the **index of refraction** of anhydrous ferric sulphate, and found for the hexagonal (trigonal) and rhombic forms :

		F-	Tl-	Na-	C-	Li-light	
$\text{Fe}_2(\text{SO}_4)_3$	Trigonal	ω	1.809	1.786	1.770	1.756	1.754
		ϵ	1.798	1.775	1.760	1.746	1.744
		α	1.844	1.819	1.802	1.787	1.785
	Rhombic	β	1.857	1.831	1.814	1.799	1.797
		γ	1.861	1.835	1.818	1.803	1.801

Fig. 670.—Dissociation Pressure of Ferric Sulphate.

G. Linck gave for the indices of refraction of the enneahydrate for red-light, $\omega=1.5469$ and $\epsilon=1.5508$; and for yellow-light, $\omega=1.5519$ and $\epsilon=1.5575$; A. Arzruni gave $\omega=1.5376$ and $\epsilon=1.5468$ for Li-light; and $\omega=1.5455$ and $\epsilon=1.5547$ for Na-light. C. Lausen gave for coquimbite, $\epsilon=1.572$ and $\omega=1.536$. E. Posnjak and H. E. Merwin gave for the heptahydrate and the hexahydrate:

		F-	Tl-	Na-	C-	Li-light
$\text{Fe}_2(\text{SO}_4)_3 \cdot 7\text{H}_2\text{O}$	α	1.585	1.578	1.572	1.566	1.565
	β	1.603	1.593	1.586	1.579	1.578
	γ	1.666	1.651	1.640	1.631	1.629
$\text{Fe}_2(\text{SO}_4)_3 \cdot 6\text{H}_2\text{O}$	α	1.624	1.613	1.605	1.598	1.597
	β	1.656	1.644	1.635	1.627	1.626
	γ	1.668	1.667	1.657	1.648	1.645

C. Lausen gave for the monoclinic crystals of the hexahydrate, lausenite, $\alpha=1.594$, $\beta=1.628$, and $\gamma=1.654$; and the optical character is negative. E. Doumer made some observations on the refractive indices of aq. soln. L. R. Ingersoll's results for a soln. of ferric sulphate of sp. gr. 1.446, at 23° ; and C. E. Richards and R. W. Roberts's results for a soln. of sp. gr. 1.190, at 17° , are, for rays of wave-length λ A.:

	Sp. gr. 1.446				Sp. gr. 1.190			
λ	12,500	10,000	8000	6000	6104	5780	5330	4958
μ	1.4061	1.4113	1.4160	1.4234	1.3728	1.3741	1.3768	1.3800

M. Kimura and M. Takewaki found that the **absorption spectrum** of anhydrous ferric sulphate shows an absorption band beginning at 4000 A. in the ultra-violet, and ending at 3400 A. E. Posnjak and H. E. Merwin added that both the trigonal and rhombic forms exhibit the same type of absorption. The colour of aq. soln. of ferric sulphate is dependent on the hydrolysis; by increasing the dilution or by raising the temp., the hydrolysis is favoured, and the colour changes from a yellowish- to a reddish-brown, and S. U. Pickering found that the intensity of the coloration with dilution increases to a maximum, and then remains constant, and as time goes on, the colour becomes darker and a turbidity appears. As pointed out by R. Weinland, the hydrolysis is reversed, and the colour of the soln. becomes paler when acid is added. J. S. Anderson found the mol. extinction coeff., k , of soln. with 1.0 and 0.1 mol per litre, in layers 0.14 and 2 cm. thick, with light of wave-length λ A.:

λ	4340	4530	4990	5630	6020	6770	7460	9000	11,750
k { 1.0	6.9	2.1	0.76	0.51	0.31	0.19	0.33	0.42	0.04
0.1	9.5	4.7	2.2	1.3	0.49	0.25	0.37	0.54	0.05

Observations were also made by T. Bayley, T. Ewan, G. Fuseya and K. Murata, R. A. Houston, R. A. Houston and C. Cochrane, R. A. Morton and R. W. Riding, and C. E. Richards and R. W. Roberts. M. Pierucci observed no spectral lines of iron when the dust of anhydrous ferric sulphate is sprayed in an arc-light.

M. Schneider found that a feebly acidified soln. of ferric sulphate is distinctly reduced by exposure to **light**, but not so much as is the case with a soln. of ferric chloride; and M. V. Dover observed that the degree of hydrolysis is perceptibly greater in light than it is in darkness. W. H. Ross found that ferric sulphate soln. are reduced to ferrous sulphate by exposure to **ultra-violet light**, and the action is greater if sugar be present. The reaction was studied by R. Audubert, A. Klemenc and H. F. Hohn. A. Kailan observed that acidic or neutral soln. of ferric sulphate are reduced to ferrous sulphate, in the presence or absence of sugar, by exposure to **radium rays**. G. L. Clark and L. W. Pickett observed no perceptible change when ferric sulphate is exposed to the **X-rays**; and A. Hébert and G. Reynaud measured the absorption of X-rays by aq. soln. of the salt. G. Reboul and E. Bodin, and E. Bodin found that rays capable of ionizing gases are emitted from pastilles of powdered, anhydrous ferric sulphate when traversed by an electric current.

L. R. Ingersoll found the **magnetic rotatory power**, i.e. the sp. magnetic rotation

of the plane of polarization, ω , for a soln. of sp. gr. 1.446 at 23°, and in a field of 12,050 gauss, for light of wave-length 12,500, 10,000, and 8000 Å. is respectively 0.0016, 0.0020, and 0.0029. C. E. Richards and R. W. Roberts observed that the magnetic rotatory power of soln. of ferric sulphate is positive, whilst the effect due to the salt is negative. There are two magnetic absorption spectral bands, one at 0.53 μ , and the other at 0.57 μ . The magnetic absorption spectra of chloride and sulphate are the same. E. Mieschier, and F. Allison and E. J. Murphy studied the magneto-optic properties.

According to R. C. Wells, the eq. **electrical conductivity**, λ , of aq. soln. of ferric sulphate for an equivalent of the salt in v litres, is :

v	1.105	9.560	16.15	38.24	48.45	145.3	300.1	600.0
λ { 0°	13.30	24.69	—	38.4	—	—	76.0	95.0
25°	24.89	45.32	—	73.2	—	—	—	—
30°	26.24	—	59.50	—	89.50	145.7	—	—

The results show that at low dilutions, the conductivity is abnormally low, whilst at high dilutions it is abnormally high. As the dilution increases, a precipitate is produced, the rate of its formation increases enormously with a rise of temp. This all agrees with the assumption that ferric sulphate begins to undergo hydrolysis at a dilution of a few litres. G. Fousereau observed that the conductivity of the soln. increases with age; and G. Carrara and G. B. Vespignani found the eq. conductivities at 25° of fresh soln., λ , and of soln. 24 hrs. old, λ' , were :

v	5	10	40	80	160	640	1280	2560
λ	36.93	47.69	67.04	99.28	127.28	225.92	298.24	404.48
λ'	—	48.61	82.88	124.64	196.64	348.16	360.96	422.40

Ferric sulphate suffers **hydrolysis** in aq. soln., but, as shown by M. Berthelot, and G. Fousereau, the aq. soln. of this salt in aq. soln. are in general more stable than is the case with aq. soln. of other ferric salts. The yellowish-brown soln. is strongly acid towards litmus, and on evaporation, it furnishes a brownish-yellow syrup, which, after a time, solidifies to a mass of indistinct crystals—partly white, partly pale yellow. The colourless octahedra reported by J. T. Cooper, and C. Sylvester, are, according to G. Forchhammer, more likely to have been ammonia or potash iron-alum. G. C. Wittstein found that the further evaporation of the soln. furnishes a brown resinous mass, which, when completely dehydrated is dirty white. If the resinous brown mass is mixed with water while still hot, it solidifies suddenly, and is more easily dried than before this treatment. According to T. Scheerer, the conc. aq. soln. does not become turbid when it is boiled, but the dil. aq. soln. do become turbid, and this the more the greater the dilution of the soln. The soln. also become turbid when boiled, and, the more dilute the soln., the lower the temp. required to produce a turbidity. A soln. with one part of the salt in 100 parts of water becomes turbid at 95°, and deposits about one-third of the solute as ferric sulphate; with 200 parts of water, the turbidity appears at about 70°, and about half the solute is deposited as ferric sulphate; with 400 parts of water, the corresponding data are 59° and three-fourths; with 800 parts of water, 50° and seven-eighths; and 1000 parts of water, 47.5° and nine-tenths. All this means that in aq. soln., ferric sulphate is hydrolyzed. Related observations were made by J. S. Anderson, S. U. Pickering, A. Recoura, R. Scharizer, E. A. Schneider, C. R. C. Tichborne, and F. Wirth and B. Bakke. According to U. Antony and G. Gigli, a clear neutral aq. soln. of ferric sulphate remains clear until highly diluted, when it becomes gradually turbid by the separation of the hydrogel of hydrated ferric oxide. During the hydrolysis basic salts are first formed, and these are ultimately converted into the insoluble hydroxide. The ferric sulphate is slowly re-formed on disturbing the state of equilibrium by adding potassium ferrocyanide, provided the soln. be not too dilute to allow of the dissolution of the hydrated ferric oxide in the sulphuric acid. F. K. Cameron and W. O. Robinson said that the precipitates—the so-called basic salts—have no well-defined composition; and U. Antony and

G. Gigli added that the hydrolysis is complete with a dilution of 1 : 60,000. According to G. Carrara and G. B. Vespignani, the degree of hydrolysis of a 22.3 per cent. soln., in the presence of hydrated ferric oxide, is 0.9 per cent. ; they also calculated, from observations on the hydrolysis of methyl acetate, that at 25°, 0.2N- $\text{Fe}_2(\text{SO}_4)_3$, a month old, contains 1.33 grms. of $\text{Fe}_2(\text{SO}_4)_3$ per 100 c.c. G. Wiedemann made observations on the percentage hydrolysis of these soln., and U. Antony and G. Gigli calculated for soln. containing grams of $\text{Fe}_2(\text{SO}_4)_3$ per 100 c.c. of soln., aged for 10 days at 10°, the percentage hydrolysis :

$\text{Fe}_2(\text{SO}_4)_3$.	.	6.7	2.0	1.0	0.50	0.10	0.050	0.025	0.0125
Hydrolysis	.	.	4	11	23	33	57	67	82	91 per cent.

R. C. Wells calculated for soln. with 6.67, 0.104, and 0.00651 grm. $\text{Fe}_2(\text{SO}_4)_3$ per 100 c.c. at 25°, the percentage hydrolysis 0, 12, and 40.0 respectively ; he also inferred from his observations of the electrical conductivity of aq. soln. that the hydrolysis proceeds in two stages embodying a rapid change unaccompanied by precipitation, and a slower change progressing at a measurable rate and accompanied by the formation of a basic sulphate. The formation of the basic salt is greatly favoured by raising the temp., or diluting the soln.

F. Seidel, and D. Vorländer observed that soln. of ferric sulphate show the Tyndall effect ; A. Quartaroli observed that when a dil. soln. is centrifuged for some hours, differences in concentration can be detected. M. V. Dover observed that the hydrolysis is greater in light than in darkness. A. Krause found that the **H'-ion concentration** of 0.1N- $\text{Fe}_2(\text{SO}_4)_3$ is $p_{\text{H}}=1.3$; on adding varying amounts of alkali—sodium or potassium-hydroxide, sodium or potassium carbonate, sodium hydrocarbonate, or aniline—to a fixed vol. of a soln. of ferric sulphate, the ratio $\text{Fe}_2\text{O}_3 : \text{SO}_3$ of the precipitate is related to the p_{H} -value or the acidity of the soln. A precipitate free from sulphate is obtained only when $p_{\text{H}} > 7.7$. On adding the theoretical proportions of sodium hydroxide or carbonate, and aq. ammonia, the values of the $\text{Fe}_2\text{O}_3 : \text{SO}_3$ ratio are respectively 24.0, 8.8, and 11.1. Ammonia in the more acidic soln. acts as a strong base—*vide infra*, the basic ferric sulphates. G. S. Tilley and O. C. Ralston observed that soln. of ferric sulphate begin to hydrolyze when the H'-ion conc. is 10^{-3} and the OH'-ion conc. is 10^{-11} , whilst hydrolysis is ended when the H'-ion conc. is 10^{-4} , and the OH'-ion conc. is 10^{-10} . W. Manchot and co-workers made observations on the **solvation** or hydration of the mol. of ferric sulphate in aq. soln., and they calculated that in soln. with 0.6874 and 1.460 mols $\text{Fe}_2(\text{SO}_4)_3$ per litre, at 25°, each mol. of $\text{Fe}_2(\text{SO}_4)_3$ is loaded respectively with 39.9 and 27.8 mols. of H_2O . J. N. Brønsted and K. Volquartz studied the complex ions $[\text{Fe}(\text{H}_2\text{O})_6]^{+++}$.

The **electromotive force** of iron electrodes in electrolytes containing ferric sulphate has been discussed previously. M. le Blanc studied the **polarization** of sulphuric acid soln. of the two iron sulphates using electrodes of gold and platinum. L. Riéty measured the difference of potential exhibited by soln. of ferric sulphate passing through capillary tubes when under a press. of 25 atm. The **electrolysis** of aq. soln. of ferric sulphate has been discussed in connection with the electro-deposition of iron. The **cathodic reduction** of ferric sulphate to ferrous sulphate with an iron cathode was studied by H. Buff, N. Kameyama and K. Takahashi, and R. Kremann and co-workers, who obtained 96 to 97 per cent. reduction in 1.5N- $\text{Fe}_2(\text{SO}_4)_3$ using a cathodic current density of 1 amp. ; only a little iron was deposited. Z. Karaoglanoff observed that the presence of ammonium sulphate had no perceptible influence on the yield. He also found that the current which just produces an evolution of hydrogen at a platinum cathode immersed in a soln. of iron-alum in 2 minutes was found to be proportional to the conc. of the soln. ; it increases by about 3 per cent. of its value per degree rise of temp. The addition of some normal salts—*e.g.* copper sulphate, silver nitrate, mercuric chloride, and more feebly, zinc sulphate, and ammonium molybdate—to the soln. increases the value of the critical currents ; in the case of copper sulphate, for example, this is

due to the deposition of copper at the cathode; other salts have no action, and a few—stannic chloride, or stannic acid—diminish the critical currents; among these, the action of the chromates is probably due to the formation of a diaphragm of chromic oxide—with potassium chromate or dichromate, small proportions accelerate and large proportions retard the action. With smooth platinum, the critical current is proportional to the surface of the electrode, hence with platinized electrodes very much larger currents can be used. A horizontal cathode gives a larger value than a vertical one. Stirring the soln. has a very marked effect in increasing the critical current. A coulometer can be constructed on the basis of these results; the anode is enclosed in a porous pot near the surface of the soln. of iron-alum in which the platinized cathode is immersed and which is stirred by a current of carbon dioxide. The ferrous salt produced is titrated with a soln. of potassium permanganate. A. Klemenc observed that in electrolysis with a gas-cathode, the reduction of the ferric salt by the hydrogen is not dependent on the presence of a solid electrode. This reduction may be due to the electrons slowly discharged from the cathode, or else in accord with $\text{Fe}^{++} + \text{H} \rightarrow \text{Fe}^{\cdot\cdot} + \text{H}^{\cdot}$. F. Oettel studied the influence of the current density on the cathodic reduction of soln. of ferric sulphate; H. C. Allen, J. C. Hostetter, A. Klemenc, and E. Nietz discussed the reversal of the action by anodic oxidation; and A. Brochet and J. Petit, O. Collenberg and S. Bodforss, and F. Pearce and C. Couchet, the reduction of the soln. of ferric sulphate by alternating currents.

M. Faraday showed that anhydrous ferric sulphate is paramagnetic; J. Plücker studied the **magnetic properties**; and G. Berndt showed that no magnetic hysteresis can be perceived in a magnetic field of 200 gauss. P. Théodorides gave 56.21×10^{-6} mass unit for the **magnetic susceptibility** of the salt. T. Ishiwara, and K. Honda and T. Ishiwara found that with a field of 2000 gauss, the magnetic susceptibility was:

	-177.3	-130.4°	-66.2°	0.1°	23.1°	210.1°	493.2°	658.2°
$\chi \times 10^{-6}$	133.2	100.2	77.1	62.7	57.3	38.6	24.9	20.9

and for a preparation with the equivalent of three-sevenths of a mol. of water, in a field between 7000 and 17,000 gauss, H. K. Onnes and E. Oosterhuis obtained:

	-208.2°	-202.6°	-195.7°	-103.5°	16.7°
$\chi \times 10^{-6}$	177.1	167.3	157.2	85.6	53.3

The results are in general agreement with the rule $\chi(T - \theta) = \text{constant}$, where θ denotes Curie's constant. The directions were discussed by R. Gans. H. K. Onnes and E. Oosterhuis showed that at low temp. the results are influenced by variations in the strength of the magnetic field.

M. Faraday showed that aq. soln. of ferric sulphate, not too dilute, are paramagnetic, but A. Quartaroli found that the diamagnetism of the water is approximately neutralized by the paramagnetism of the ferric sulphate when the soln. contains about 2.80 grms. of Fe per litre. Observations on the magnetic susceptibility of aq. soln. of ferric sulphate were made by E. Becquerel, H. Breternitz, J. Plücker, P. Théodorides, and G. Wiedemann. B. Cabrera and E. Moles found the susceptibility of soln. of ferric sulphate, at 20°, to be:

$\text{Fe}_2(\text{SO}_4)_3$	0.3508	0.4668	1.173	2.326	3.380	6.678	11.26	15.38	per cent.
$\chi \times 10^{-6}$	-0.5132	-0.4439	-0.0137	0.6989	1.3822	3.4541	6.4507	9.0020	
$\chi_A \times 10^{-6}$	11,660	11,710	11,940	12,110	12,260	12,410	12,640	12,550	

J. S. E. Townsend observed a linear relation between the dilution and the magnetic susceptibility of soln. at 10° in a field between 1 and 9 gauss. For the atomic susceptibility χ_A , B. Cabrera and E. Moles gave the results indicated above. A. Quartaroli obtained for the mol. susceptibility, χ_m , of soln. with a mol of $\text{Fe}_2(\text{SO}_4)_3$ in v litres, at 18°:

v	10	20	50	100	250	500	750	1,000
$\chi_m \times 10^{-6}$	14,386	13,344	13,116	12,756	12,088	10,528	11,635	11,375

O. Liebknecht and A. P. Wills gave 38×10^{-6} mass unit for the susceptibility, or $15,150 \times 10^{-6}$ for the mol. susceptibility, of an aq. soln. of ferric sulphate with 0.97 per cent. $\text{Fe}_2(\text{SO}_4)_3$, from which R. H. Weber calculated the at. susceptibility of the iron to be $15,210 \times 10^{-6}$, and J. S. E. Townsend gave 75×10^{-6} mass unit for the magnetic susceptibility at 10° . A. Heydweiller obtained 37.9×10^{-6} vol. unit for a soln. of sp. gr. 1.609 at 10.8° in a magnetic field of 0.181 to 1.13 gauss; and O. Wylach gave 30.2×10^{-6} vol. unit. B. Cabrera and E. Moles examined the effect of sulphuric acid on the susceptibility of soln. with 1.571 to 1.590 per cent. of $\text{Fe}_2(\text{SO}_4)_3$ at 20° when the acid ratio indicates mols H_2SO_4 : mols $\text{Fe}_2(\text{SO}_4)_3$:

Acid ratio .	0.0994	0.1989	0.3901	0.7752	1.2087	1.9998	2.4227	4.8477
$\chi \times 10^{-6}$.	2.7535	3.0390	3.2180	3.7540	4.0043	4.2345	4.1424	4.3877

G. Wiedemann, R. H. Weber, B. Cabrera and E. Moles, and J. S. E. Townsend measured the effect of temp. on the magnetic susceptibility of aq. soln. of ferric sulphate; and it was found to decrease with a rise of temp. A. E. Oxley represented the susceptibility χ at $T^\circ \text{K.}$ by $\chi = aT^{-1} + b$, where a and b are constants. A. Heydweiller found that whilst the effect of variations in the strength of the magnetic field is imperceptible with small variations—say 0.18 to 1.1 gauss—yet over the range $H=0.1$ to 40,000 gauss, the susceptibility changes about 30 per cent. Observations were also made by J. S. E. Townsend, O. Wylach, and R. H. Weber.

K. Honda and T. Ishiwara calculated the **magnetic moment** of a mol of $\text{Fe}_2(\text{SO}_4)_3$ to be 7.42×10^{-20} , whilst H. K. Onnes and E. Oosterhuis' measurements gave 10^{-20} . R. Gans calculated 3656 for the **magneton number** of anhydrous ferric sulphate, and P. Théodoridès, 28.97 between 0° and 250° , and 28.93 between 70° and 550° . Calculations from observations on aq. soln. were made by B. Cabrera and E. Moles, A. Quartaroli, R. H. Weber, and P. Weiss.

The chemical properties of ferric sulphate.—The reduction of soln. of ferric sulphate by nascent **hydrogen** follows similar lines to the case of ferric chloride. D. Tommasi noted that the salt is partially reduced by detonating gas. J. Eggert observed that in the absence of a catalyst no hydrogen was absorbed by a 0.1*N*-soln. of ammonium ferric sulphate; R. Böttger observed that nickel charged with hydrogen reduced the salt in soln. to ferrous sulphate; and similar results with palladium charged with hydrogen were obtained by W. Fresenius, W. H. Gintl, T. Graham, A. Hoenig, L. Kritschewsky, and K. I. Lissenko. The reduction with palladium charged with hydrogen was found by A. C. Chapman to be complete in 20 to 30 mins.; but W. H. Gintl found that by passing hydrogen into a boiling soln. of ferric sulphate, containing a piece of palladium, the reduction is very slow. S. Cooke, J. Eggert, and W. H. Gintl also found that a soln. of ferric sulphate is readily reduced by hydrogen in the presence of platinized platinum, or platinum sponge. J. H. Weibel studied the action of hydrogen under press. on the soln.

D. Florentin, M. Lachaud and C. Lepière, and F. Wirth and B. Bakke noted that anhydrous ferric sulphate is hygroscopic when exposed to **air**, but G. Keppeler and J. d'Ans found that if free sulphuric acid be absent, the salt is not particularly hygroscopic. J. Milbauer and O. Quadrat observed only a slight superficial change when the anhydrous sulphate is exposed in a current of dry air, but with moist air, water is rapidly absorbed forming, according to F. K. Cameron and W. O. Robinson, the decahydrate. A. Recoura found that when the white ferric sulphate is exposed to moist air it slowly forms the white and then the yellow enneahydrate; yellow ferric sulphate takes up water more rapidly than the white form producing the trihydrate. E. Posnjak and H. E. Merwin observed that both rhombic and hexagonal ferric sulphates slowly absorb water when exposed to air. For the action of air on the heated sulphate, *vide supra*.

The observations of J. S. Anderson, G. T. Gerlach, M. Lachaud and C. Lepière, and C. R. C. Tichborne show that anhydrous ferric sulphate is dissolved by **water**

very slowly, yielding a brown soln., and hence C. F. Bucholz, D. Florentin, and F. Ulrich wrongly thought that the solubility of the salt in water is very small. According to F. Wirth, 18.57 parts of water dissolve 81.43 parts. N. R. Dhar observed that the rate of solution of anhydrous ferric sulphate in water can be accelerated by the presence of a trace of the reducing agents—stannous chloride or ferrous sulphate, or of the enneahydrate, coquimbite. A. C. Oudemans also observed that the decahydrate, quenstedtite, is slowly dissolved by water. S. U. Pickering found that the rate of solution of the anhydrous sulphate in water is accelerated by raising the temp.; and L. C. A. Barreswil showed that the rate of solution of the anhydrous salt in water is considerably hastened if a little ferrous sulphate be present. G. Keppeler and J. d'Ans, and N. R. Dhar added that reducing agents like hydroxylamine, sulphur dioxide, and stannous chloride act similarly, presumably in consequence of the formation of some ferrous sulphate. A. Laurent, and A. Recoura reported that the anhydrous salt exists in at least three different molecular states distinguished by very different solubilities in water. It has been suggested that L. C. A. Barreswil's observation explains the results. A. Recoura's products were possibly contaminated with variable proportions of ferrous salts. M. Berthelot, and A. and P. Buisine inferred that the slowness of the process of dissolution of the anhydrous salt in water is due to the need for a preliminary hydration; and A. Recoura, a preliminary depolymerization of the salt. A. and P. Buisine observed that when stirred with a little water, the anhydrous sulphate sets as if it were a kind of plaster of paris. The hydrolysis of the salt in aq. soln. has been previously discussed. V. L. Bohnson studied the catalytic decomposition of **hydrogen dioxide** by ferric sulphate—*vide supra*, ferric chloride. H. Kwasnik found that an aq. soln. of ferric sulphate reacts with **barium dioxide** giving off oxygen, and forming hydrated ferric oxide—*vide* the action of ferric chloride on hydrogen dioxide.

K. H. Butler and D. McIntosh found that anhydrous ferric sulphate is not soluble in liquid **chlorine**. C. Hensgen observed that **hydrogen chloride** decomposes anhydrous ferric sulphate neither at ordinary temp., nor at 100°. L. C. A. Barreswil said that ferric sulphate is insoluble in conc. **hydrochloric acid**; and A. Recoura, that with boiling conc. hydrochloric acid, the acid salt $\text{Fe}_2\text{O}_3 \cdot 4\text{SO}_3 \cdot 9\text{H}_2\text{O}$ is formed. O. Röhm obtained **ferric chlorosulphate**, $\text{Fe}(\text{SO}_4)\text{Cl} \cdot 6\text{H}_2\text{O}$, from a mixture of ferric chloride, sulphuric acid, and water in the mol. proportions 1 : 1 : 6; or from a mixture of ferric chloride and sulphate, and water in the mol. proportions 1 : 1 : 18. C. E. Schafhäütl observed that when a soln. of ferric sulphate is mixed with **sodium chloride**, it evolves hydrogen chloride at 60°, and if it be evaporated to dryness, and heated in air, chlorine is evolved, and a mixture of sodium sulphate and ferric oxide remains. E. Kothny also found that a dry mixture of ferric sulphate and sodium chloride gives off ferric chloride at 285°, but L. C. Jones and G. N. Terzieff found that if the mixture is heated in the presence of oxygen or air, chlorine is evolved. C. F. Schönbein observed that a mixture of ferric sulphate and **potassium iodide** reacts in the cold with the evolution of iodine, the reaction is vigorous when the mixture is warmed; no sulphur dioxide was formed. K. Seubert and R. Rohrer represented the reaction: $2\text{Fe}_2(\text{SO}_4)_3 + 2\text{KI} = 2\text{FeSO}_4 + \text{K}_2\text{SO}_4 + \text{I}_2$, where, according to K. Seubert and A. Dorrer, and E. I. Orloff, it is possible that **ferric iodosulphate**, $\text{Fe}(\text{SO}_4)\text{I}$, is formed as an intermediate product: $(\text{FeSO}_4)_2\text{SO}_4 + 2\text{KI} = \text{K}_2\text{SO}_4 + 2\text{Fe}(\text{SO}_4)\text{I}$, followed by $2\text{Fe}(\text{SO}_4)\text{I} = 2\text{FeSO}_4 + \text{I}_2$. O. Röhm, and B. Walther prepared what was regarded as ferric chlorosulphate, $\text{Fe}(\text{SO}_4)\text{Cl} \cdot 6\text{H}_2\text{O}$, by the action of chlorine on a soln. of ferrous sulphate, and from a soln. of equimolar parts of ferric chloride and sulphate. The salt has been used in the tanning industry. A. Skrabal, and E. Fleischer represented the action of **cuprous iodide** on a boiling soln. of ferric sulphate by: $2\text{Fe}_2(\text{SO}_4)_3 + \text{Cu}_2\text{I}_2 = 2\text{CuSO}_4 + 4\text{FeSO}_4 + \text{I}_2$. M. Hersch-kowitsch found that when a mixture of ferric sulphate and **potassium chlorate** is moistened and heated to 100°, chlorine dioxide mixed with a little chlorine is evolved. S. E. Moody observed that when a soln. of ferric sulphate is boiled with

potassium iodate and iodide, hydrolysis occurs: $\text{Fe}_2(\text{SO}_4)_3 + 5\text{KI} + \text{KIO}_3 + 3\text{H}_2\text{O} = 2\text{Fe}(\text{OH})_3 + 3\text{K}_2\text{SO}_4 + 3\text{I}_2$.

K. Brückner observed that when ferric sulphate is melted with **sulphur**, sulphur dioxide and iron sulphide are formed. Ferric sulphate—*vide supra*, ferric chloride—is reduced by **sulphur dioxide** or by a **sulphite** and a little mineral acid: $\text{Fe}_2(\text{SO}_4)_3 + \text{SO}_2 + 2\text{H}_2\text{O} = 2\text{FeSO}_4 + 2\text{H}_2\text{SO}_4$. The reducing action of a **thiosulphate** on ferric sulphate: $2\text{Fe}^{+++} + 2\text{S}_2\text{O}_3^{--} = 2\text{Fe}^{++} + \text{S}_4\text{O}_6^{--}$, was shown by J. T. Hewitt and G. R. Mann to be a tetramolecular reaction. The reaction was studied by J. Pinnow. According to L. C. A. Barreswil, ferric sulphate is insoluble in conc. **sulphuric acid**; and C. F. Bucholz found that the salt is soluble in aq. soln. of sulphuric acid, and when the soln. is evaporated, it furnishes a deliquescent, soluble, white powder—probably an acid sulphate. A. W. Davidson observed that ferric sulphate is very sparingly soluble in 100 per cent. H_2SO_4 , and the suspension of ferric sulphate in 100 per cent. H_2SO_4 gives neither the thiocyanate nor the prussian blue reaction. F. Wirth showed that 2·25N-, 6·685N-, and 19·84N- H_2SO_4 dissolve respectively 25·02, 14·50, and 0·05 grms. $\text{Fe}_2(\text{SO}_4)_3$ per 100 grms. of soln. The equilibrium conditions in the system Fe_2O_3 - SO_3 - H_2O at different temp. have been previously discussed—Figs. 661 to 668. A number of acid salts have been reported. G. C. Weltzien, and A. Hoffmann reported $\text{Fe}_2\text{O}_3 \cdot 5\text{H}_2\text{O}$ and $\text{Fe}_2\text{O}_3 \cdot 6\text{SO}_3 \cdot 11\text{H}_2\text{O}$, or $\text{Fe}_2(\text{SO}_4)_3 \cdot 3\text{H}_2\text{SO}_4 \cdot 8\text{H}_2\text{O}$; but the equilibrium diagrams show with certainty the existence of $\text{Fe}_2\text{O}_3 \cdot 4\text{SO}_3$ and of the ennea- and trihydrates. A. Hoffmann, A. Recoura, M. C. Schuyten, and P. Marguerite-Delacharlionny described hydrates with 1, 4, 8, and 12 mols. of water; but these do not appear on the equilibrium diagram.

J. A. Krenner found an acid ferric sulphate occurring with the other iron sulphates at Szomolnok, Hungary; its composition approximated that of **ferric tetrasulphate**, $\text{Fe}_2\text{O}_3 \cdot 4\text{SO}_3 \cdot 9\text{H}_2\text{O}$; and it was called **rhomboclase**. R. Scharizer observed that the *enneahydrate* is the stable phase, at ordinary temp., with soln. containing 0·43 per cent. Fe_2O_3 , 37·42 per cent. SO_3 , and 62·15 per cent. H_2O . Expressing the proportions of these constituents in percentages, the enneahydrated tetrasulphate was found to be the stable phase with soln. within the following ranges of composition: W. P. Applebey and S. H. Wilkes gave 0·21 to 9·63 Fe_2O_3 , 40·64 to 31·88 SO_3 , and 59·15 to 58·49 H_2O at 18°—*vide* Fig. 661; and at 25°, 0·25 to 8·0 Fe_2O_3 , 40 to 32·2 SO_3 , and about 59·8 H_2O —*vide* Fig. 662. F. K. Cameron and W. O. Robinson gave 1·05 to over 10·87 Fe_2O_3 , 42·43 and below 31·35 SO_3 , and 56·52 to 57·78 H_2O at 25°; and F. Wirth and B. Bakke, 3·53 to 9·39 Fe_2O_3 , 34·00 to 31·54 SO_3 , and 62·47 to 59·07 H_2O at 25°. E. Posnjak and H. E. Merwin gave at 50°, 0·7 to 7·5 Fe_2O_3 , 57·00 to 33·0 SO_3 , and 42·3 to 59·5 H_2O —Fig. 667; at 75°, 0·1 to 45·9 Fe_2O_3 , 55·5 to 35·51 SO_3 , and 46·4 to 59·90 H_2O —Fig. 666; and at 110°, 0·3 to 1·0 Fe_2O_3 , 56·0 to 43·0 SO_3 , and 43·7 to 56·0—Fig. 665. The salt was obtained from sulphuric acid soln. of ferric sulphate by V. Komar, A. Recoura, R. Scharizer, G. McPhail Smith, R. F. Weinland and F. Ensgraber, and F. Wirth and B. Bakke. The mush of white or yellowish-white crystals is drained on a porous tile, washed with acetone or alcohol, and dried in air or over conc. sulphuric acid. R. Scharizer evaporated in air a soln. containing the mol. proportion $\text{Fe}_2\text{O}_3 : \text{SO}_3 = 1 : 4$, and obtained what he regarded as the *henahydrate*: $\text{Fe}_2\text{O}_3 \cdot 4\text{SO}_3 \cdot 11\text{H}_2\text{O}$; this passed into the enneahydrate when kept over sulphuric acid for 24 hrs. He also said that the enneahydrate is obtained by treating the henahydrate with alcohol, or by evaporating the alcoholic soln. A. Recoura obtained the enneahydrate from a soln. of ferric sulphate in boiling conc. hydrochloric acid; and M. P. Applebey and S. H. Wilkes, from a sulphuric acid soln. of ferrous sulphate treated with nitric acid and evaporated in a desiccator. According to F. Wirth and B. Bakke, the fine powder is white, but the coarse powder is pale rose-red, and by contact with water, the salt forms yellowish-white needles. E. Posnjak and H. E. Merwin, R. Scharizer, and R. F. Weinland and F. Ensgraber found that under the microscope the crystals appear to be thin plates, and less

often they appear in aggregates of needles. J. A. Krenner said that rhomboclase occurs in clear, white, scaly crystals. R. Scharizer reported that the crystals are monoclinic with axial ratios $a:b:c=0.4633:1:0.7416$, and $\beta=89^\circ 6'$; whilst E. Posnjak and H. E. Merwin showed that the crystals are rhombic, not monoclinic, and have the axial ratios $a:b:c=0.563:1:0.940$. The lozenge-shaped, tabular crystals have the base and pyramid as prominent forms, and unit prism and pinacoid are usually present. The basal or (001)-cleavage is marked, and there is a fibrous prismatic or (110)-cleavage. The optic axial angle $2V$ is small, and the crystals are pleochroic—yellow in the directions γ and β , and purple in the α direction. R. Scharizer observed that the birefringence is strong— $\mu_\gamma-\mu_\beta=0.099$ —but decreases slowly as the crystals are heated above 70° . The sp. gr. is 2.172 at 16.4° ; and the hardness is 2.0. The indices of refraction are $\beta=1.551$, and $\gamma=1.650$. E. Posnjak and H. E. Merwin gave for the indices of refraction:

	F.	Tl.	Na.	C.	Li-light
α	1.545	1.538	1.533	1.529	1.528
β	1.564	1.556	1.550	1.545	1.544
γ	1.657	1.644	1.635	1.626	1.625

F. Wirth and B. Bakke showed that the enneahydrate quickly loses water on exposure to air, and R. Scharizer, and F. Wirth and B. Bakke found that when confined over sulphuric acid for about six months, 5 mols. of water are removed. R. Scharizer said that the enneahydrate loses 5 mols. of water at 64° . F. Wirth and B. Bakke found that 6 mols. of water are lost below 98° ; and A. Recoura observed that 6 mols. are lost between 80° and 100° . The remaining 3 mols. of water are driven off along with a mol. of SO_3 at 135° , and anhydrous ferric sulphate remains. R. Scharizer thought that the *monohydrate*, $\text{Fe}_2\text{O}_3 \cdot 4\text{SO}_3 \cdot \text{H}_2\text{O}$, is formed at 128° . A. Recoura also thought that the tetrasulphate passes into the normal, anhydrous sulphate when heated in conc. sulphuric acid to 250° . R. Scharizer tried to discriminate between the constitutional water, and the water of crystallization of the enneahydrate, and, instead of the formula: $\text{Fe}_2\text{O}_3 \cdot 4\text{SO}_3 \cdot 9\text{H}_2\text{O}$, he wrote: $(\text{HO})_6\text{Fe}_2\text{S}_4\text{O}_{12} \cdot 6\text{H}_2\text{O}$, or $\{(\text{HO})\text{Fe}\}_2(\text{HSO}_4)_4 \cdot 6\text{H}_2\text{O}$, or more simply $\text{HO} \cdot \text{Fe}(\text{HSO}_4)_2 \cdot 3\text{H}_2\text{O}$, or *ferric hydroxybisulphate*. A. Recoura regarded the tetrasulphate as a dibasic acid, *ferrisulphuric acid*, which forms esters. It resembles chromosulphuric acid, but is more readily decomposed by water. When the tetrasulphate is dissolved in 96 per cent. alcohol, and the soln. is evaporated over conc. sulphuric acid, in vacuo, it furnishes a yellow, friable salt, *ethyl ferrisulphate*, $\text{Fe}_2(\text{SO}_4)_3 \cdot (\text{C}_2\text{H}_5)_2\text{SO}_4 \cdot 4\text{H}_2\text{O}$. R. F. Weinland and F. Ensgraber described a series of salts of what they called *disulphatoferric acid*, $\text{H}[\text{Fe}(\text{SO}_4)_2] \cdot 4\text{H}_2\text{O}$, or $\text{HSO}_4 \cdot \text{Fe} : \text{SO}_4 + 4\text{H}_2\text{O}$; and R. Scharizer's formula: $\text{Fe}(\text{OH})(\text{HSO}_4)_2$, can be written as a hydroxydisulphatoferric acid, $\text{H}_2[\text{Fe}(\text{OH})(\text{SO}_4)_2]$, which furnishes salts like *sideronatriite*, $\text{Na}_4\text{Fe}_2\text{S}_4\text{O}_{12} \cdot 7\text{H}_2\text{O}$, or $\text{Na}_2[\text{Fe}(\text{OH})(\text{SO}_4)_2] \cdot 3\text{H}_2\text{O}$, and *römerite*, $\text{RFe}_2\text{S}_4\text{O}_{16} \cdot 14\text{H}_2\text{O}$ —*vide infra*. R. Scharizer observed that the salt attracts moisture from the atmosphere, and dissolves undecomposed in the absorbed water; but F. Wirth and B. Bakke added that the salt is partially hydrolyzed by water vapour. R. Scharizer said that the aq. soln. is readily undercooled. M. P. Applebey and H. S. Wilkes found that the solubility of the salt in water is rapidly depressed by increasing the proportion of added sulphuric acid, and in the presence of 38 per cent. SO_3 , the salt is almost insoluble at 18° , and likewise in the presence of 40 per cent. SO_3 at 25° . The hydrolysis was studied by M. P. Applebey and S. H. Wilkes, A. Recoura, and R. Scharizer. When diluted or heated, the aq. soln. shows the same colour-changes as those exhibited by the normal sulphate; the mol. lowering of the f.p. is the additive result of the values for the components; R. Scharizer found that the hydrolysis of the salt in aq. soln. furnishes the basic salt copiapite, $\text{Fe}_4\text{S}_5\text{O}_{21} \cdot 48\text{H}_2\text{O}$; the hydrolysis is prevented by sulphuric acid; and F. Wirth and B. Bakke found that at 25° , the presence of more than 1:6.699 acid is necessary for the salt to be stable—*vide supra*. R. Scharizer observed that the enneahydrate dissolves slowly in alcohol; and it is less soluble

in that menstruum than is copiapite or coquimbite; and F. Wirth and B. Bakke added that 100 grms. of a sat. soln. of the salt in alcohol, at 25°, contain 8 grms. Fe_2O_3 and 17.18 grms. SO_3 . A. Recoura said that with 90 per cent. alcohol, the complex: $\text{Fe}_2\text{O}_3 \cdot 3\text{SO}_3 \cdot (\text{C}_2\text{H}_5)_2\text{SO}_4 \cdot 4\text{H}_2\text{O}$, is formed. R. Scharizer observed that acetone extracts sulphuric acid from the salt.

E. Posnjak and H. E. Merwin observed that small needles of a trihydrate, $\text{Fe}_2\text{O}_3 \cdot 4\text{SO}_3 \cdot 3\text{H}_2\text{O}$, are stable in soln. with the percentage proportions: 0.07 Fe_2O_3 , 75.37 to 57.0 SO_3 , and 24.56 to 42.3 H_2O at 50°; 0.07 to 0.1 Fe_2O_3 , 74.14 to 55.5 SO_3 , and 25.79 to 44.4 H_2O at 75°; and 0.06 to 0.3 Fe_2O_3 , 72.5 to 56.0 SO_3 , and 27.44 to 43.7 H_2O at 110°. It is stable in contact with its aq. soln. up to 140°—Figs. 661 to 667. R. Scharizer said that at 10°, the trihydrate is stable in contact with soln. containing over 67 per cent. H_2SO_4 ; and F. Wirth and B. Bakke thought that it might be present in soln. with 3.53 Fe_2O_3 , 34.00 SO_3 , and 62.47 H_2O at 25°. R. Scharizer, and F. Wirth and B. Bakke observed that the trihydrate is formed, as indicated above, when the enneahydrate is kept over conc. sulphuric acid for some months, or, according to R. Scharizer, and A. Recoura, by heating the enneahydrate between 64° and 100°. A. Recoura also prepared a salt which may have been the trihydrate, or a ferrisulphuric acid, by adding 3 mols of sulphuric acid to a conc. soln. of a mol of ferric sulphate. The brown soln. gradually becomes colourless and deposits a white powder. The same product is obtained when the proportion of sulphuric acid is varied. J. Poizat studied the action of this salt on hydrogen dioxide. R. Scharizer said that the trihydrate forms thin, pale red plates or tabular monoclinic crystals; and E. Posnjak and H. E. Merwin observed that the crystals appear in the form of fine needles. R. Scharizer said that the crystals are biaxial, and that the optical character is feebly negative. The sp. gr. is 2.549. When exposed to air, water is absorbed and a skin of the enneahydrate is formed on the crystals. A. Recoura found that the trihydrate dissolves slowly in water. I. S. Teletoff and V. M. Simonova, and J. Poizat studied its action on hydrogen dioxide. H. Ungemach described the mineral **leucoglaukite**, $\text{Fe}_2\text{O}_3 \cdot 4\text{SO}_3 \cdot 5\text{H}_2\text{O}$, from Tierra Amarilla, Chili, with pale blue, hexagonal crystals with $a:c=1:0.5589$.

In 1823, G. Forchhammer reported a compound of ferric oxide, **ammonia**, and sulphuric acid. According to G. Gore, H. McKee Elsey, and E. C. Franklin and

FIG. 671. — Thermal Dissociation of the Ammines of Ferric Sulphate.

C. A. Krause, anhydrous ferric sulphate is insoluble in liquid ammonia. F. Ephraim, and F. Ephraim and S. Millmann studied the ammines of ferric sulphate. A mol. of anhydrous ferric sulphate can absorb about 13 mols. of ammonia to form a voluminous, brown mass, which suffers no perceptible change on standing 16 hrs. in liquid ammonia. The product formed below 0° corresponds approximately with **ferric dodecamminesulphate**, $\text{Fe}_2(\text{SO}_4)_3 \cdot 12\text{NH}_3$; at temp. between 20° and 160°, Fig. 671, it breaks down into **ferric hexamminesulphate**, $\text{Fe}_2(\text{SO}_4)_3 \cdot 6\text{NH}_3$; and this in turn at temp. between 193° and 198°, furnishes **ferric tetramminesulphate**, $\text{Fe}_2(\text{SO}_4)_3 \cdot 4\text{NH}_3$; and between 200° and 300°, the tetrammine yields **ferric diammino-**

sulphate, $\text{Fe}_2(\text{SO}_4)_3 \cdot 2\text{NH}_3$. G. Spacu obtained ferric octamminesulphate, $\text{Fe}_2(\text{SO}_4)_3 \cdot 8\text{NH}_3 \cdot 4\text{H}_2\text{O}$, or $[(\text{H}_2\text{O})_2\text{Fe}(\text{NH}_3)_4]_2(\text{SO}_4)_3$, by exposing powdered enneahydrated ferric sulphate to the action of dry ammonia. The dark reddish-brown, amorphous powder loses a part of its ammonia when exposed to air; it is insoluble in water, but is gradually hydrolyzed in contact with that liquid; it is soluble in dil. sulphuric acid; somewhat soluble in acetic acid; and insoluble in carbon disulphide, toluene, xylene, methyl, ethyl, and amyl alcohols, and in ether, acetone, chloroform, aniline, and pyridine. H. W. Kohlshütter studied the reaction: $\text{Fe}_2(\text{SO}_4)_3 \text{cryst.} + 6\text{NH}_4\text{OH soln.} = \text{Fe}_2\text{O}_3 \cdot n\text{H}_2\text{O} + 3(\text{NH}_4)_2\text{SO}_4 + m\text{H}_2\text{O}$.

T. W. B. Welsh and J. H. Broderson found that ferric sulphate is soluble in dry

hydrazine, and the soln. is decomposed by sodium with the precipitation of iron. T. Curtius and F. Schrader observed that hydrazine hydrate reduces a soln. of ferric sulphate rapidly to the ferrous state, and if an excess is added, green ferrous hydroxide is precipitated. E. J. Cuy also studied the reaction. T. Curtius and J. Rissom, and L. M. Dennis and A. W. Browne noted that **sodium azide** with a soln. of ferric sulphate gives blood-red ferric azide. W. Manchot and co-workers observed that soln. of ferric sulphate containing 0, 26.390, and 52.781 grms. of $\text{Fe}_2(\text{SO}_4)_3$ per 100 c.c. absorb respectively 53.3, 25.9, and 13.1 c.c. of **nitrous oxide** per 100 c.c. of soln. W. Manchot showed that a soln. of ferric sulphate in 90 per cent. sulphuric acid dissolves **nitric oxide** forming a red soln. considered to be **ferric tetranitrosylsulphate**, $\text{Fe}_2(\text{SO}_4)_3 \cdot 4\text{NO}$. J. Napier observed that **arsenic** is attacked by a soln. of ferric sulphate. A soln. of ferric sulphate is reduced by **arsenic trioxide** to the ferrous state. J. Napier observed that, unlike the case with ferric chloride, neutral soln. of ferric sulphate, cold or hot, do not dissolve very much **antimony**. J. Hanus observed that when ferric sulphate is heated with **antimony trisulphide** the reaction may be symbolized : $\text{Sb}_2\text{S}_3 + 5\text{Fe}_2(\text{SO}_4)_3 + 8\text{H}_2\text{O} = 2\text{H}_3\text{SbO}_4 + 10\text{FeSO}_4 + 5\text{H}_2\text{SO}_4 + 3\text{S}$. J. Napier found that neutral soln. of ferric sulphate dissolve some bismuth; and L. L. de Koninck showed that an acidic soln. dissolves some **bismuth** and is simultaneously reduced to ferrous sulphate. K. Someya found that in an atm. of carbon dioxide, an acidified soln. of ammonium ferric sulphate is reduced quantitatively by **bismuth amalgam**; and if a molybdenum salt is present as catalyst, the reduction proceeds quantitatively in air. J. Hanus represented the reaction with **bismuth trisulphide** : $\text{Bi}_2\text{S}_3 + 3\text{Fe}_2(\text{SO}_4)_3 = 6\text{FeSO}_4 + \text{Bi}_2(\text{SO}_4)_3 + 3\text{S}$.

C. F. Schönbein, and E. Heymann and co-workers said that soln. of ferric sulphate are completely reduced by powdered **carbon**, but P. Rona and L. Michaelis observed only a slight reduction, and they added that the charcoal adsorbs the Fe^{+++} -ions but not so readily as is the case with Hg^{++} -ions or Ag^+ -ions. J. H. Weibel studied the action of **carbon monoxide** on soln. of the salt. W. Manchot and co-workers found that soln. containing 0, 26.390, and 52.781 grms. $\text{Fe}_2(\text{SO}_4)_3$ per 100 c.c. of soln. absorb respectively 95.7, 45.8, and 22.7 c.c. of **acetylene** per 100 c.c. According to A. Recoura, 96 per cent. **alcohol** dissolves the white form of anhydrous ferric sulphate in many months, the yellow form in 3 or 4 days, and the white modification of the enneahydrate in about a month; and the soln., in vacuo, deposits the complex : $\text{Fe}_2\text{O}_3 \cdot 3\text{SO}_3 \cdot 2\text{C}_2\text{H}_5\text{OH} \cdot 2\text{H}_2\text{O}$. The yellow form of the enneahydrate dissolves in 96 per cent. alcohol in 24 hrs. forming the soluble acid sulphate, $\text{Fe}_2\text{O}_3 \cdot 4\text{SO}_3$, and the insoluble basic sulphate, $6\text{Fe}_2(\text{SO}_4)_3 \cdot \text{Fe}_2\text{O}_3$; the salt dissolves in absolute alcohol without decomposition. The red alcoholic soln. of ferric sulphate when exposed in a closed vessel to light was found by T. von Grotthus to be slowly reduced to a pale yellow soln. containing ferrous sulphate, but in darkness no change was observed. E. Müller and O. Diefenthaler observed no perceptible reduction occurred when an alcoholic soln. containing hydrochloric acid was heated. A. W. Davidson observed that the salt is insoluble in **acetic acid**. The salt is precipitated from its aq. soln. by acetic acid; and A. Recoura prepared a complex salt by the action of **acetic anhydride** on the enneahydrate. A. Naumann and M. Hamers, and M. Hamers found that ferric sulphate is insoluble in dry **methyl or ethyl acetate**, or in ethyl acetate sat. with water at 18° ; A. Naumann and W. Eidmann, and W. Eidmann, that the salt is insoluble in **acetone**; A. Conduché, that when ferric sulphate is heated in **chloroform**, ferrous and ferric chlorides are formed; G. Lemoine, that when ferric sulphate is mixed with **oxalic acid** and heated, carbon dioxide is evolved, and ferrous sulphate is formed—water accelerates the reaction; and S. Hakomori studied the action of oxalic acid, of **citric acid**, and of **malic acid**. G. Spacu showed that the salt forms a complex, $\text{Fe}_2(\text{SO}_4)_3 \cdot 5\text{C}_6\text{H}_5\text{NH}_2 \cdot 6\text{H}_2\text{O}$, with **aniline**; A. Naumann and J. Schröder, and J. Schröder, that the salt is insoluble in **pyridine**; G. Spacu, that it forms complexes with pyridine; H. McKee Elsey, that it is insoluble in **methylamine** and **ethyl-**

amine; and F. Blau, that it forms complex salts with *aa'*-**dipyridyl** and with **α -phenanthroline**. G. Fuseya and co-workers detected complex cation formation with **glycine**. F. Rohart observed that ferric sulphate is adsorbed from its aq. soln. by **animal or vegetable substances**, and this so tenaciously, that it cannot be extracted by hydrochloric acid, and it does not give a precipitate of barium sulphate when digested with a boiling soln. of barium chloride. Meat treated with ferric sulphate retains its red colour, and becomes hard enough to resist scratching by the finger-nail.

According to C. G. Schluederberg, and J. Napier, **copper** is readily dissolved by a soln. of ferric sulphate, and the action is not affected by light. The surface action on the copper is almost instantaneous so that the observed speed of dissolution is governed by the rate of stirring. The reaction was studied by D. Nishida, and S. A. Pletenew and W. N. Rosow. L. Gmelin stated that on boiling a soln. of ferric sulphate with **silver**, ferrous and silver sulphates are formed, but, as the liquid cools, the silver is again precipitated, and ferric sulphate re-formed—*vide supra*, the action of silver sulphate on ferrous sulphate. According to P. C. McIlhiney, when **gold** is dissolved by hydrochloric acid in the presence of a ferric salt, the latter acts as a carrier of chlorine. J. Napier studied the action. Z. Roussin found that an acidified soln. of ferrous sulphate is rapidly reduced by **magnesium** forming ferrous sulphate, and some iron which appears as a black film on the magnesium, and which soon dissolves. The reaction was studied by A. Hoenig, and W. N. Hartley. A. W. Beshgetoor said that no iron is formed if too great an excess of acid is not present and the soln. is cooled. T. E. Thorpe, and S. Sugden observed that the reducing action is favoured by a rise of temp., and an increasing concentration of the ferric salt and is retarded by reducing the concentration of sulphuric acid. J. Napier found that the soln. is also reduced by **zinc**, and **cadmium**; and A. Hoenig, S. Sugden, and T. E. Thorpe said that the reaction resembles the case with magnesium—*vide ferric chloride*. L. W. McCay and W. T. Anderson represented the reaction between **mercury** and a soln. of ferric sulphate to which sulphuric acid has not been added, by the equation: $\text{Fe}_2(\text{SO}_4)_3 + \text{Hg} \rightleftharpoons 2\text{FeSO}_4 + \text{HgSO}_4$. The reduction is complete in the presence of hydrochloric or sulphuric acid and an equivalent amount of alkali chloride. D. Borar observed that in the absence of hydrochloric acid, mercury does not reduce a soln. of iron-alum. P. C. Ray showed that the presence of a trace of ferric sulphate retards the dissolution of mercury in nitric acid. K. Masuda studied the reduction of the soln. by **zinc amalgam**. A. Hoenig observed that ferric sulphate in soln. is completely reduced to ferrous sulphate by **aluminium**, and, as in the case of zinc and magnesium, a black film of iron forms on the metal. The reaction was also studied by W. Scott, and by W. Heller. J. Napier found that a neutral soln. of ferric sulphate is readily reduced by **tin** as the tin passes into solution; the action is hastened by heat. I. A. Lösner also found that a sat. soln. of ferric sulphate rapidly dissolves tin. J. Napier showed that a neutral soln. of ferric sulphate dissolves **lead** and is itself reduced to ferrous sulphate, but a protective film of lead sulphate is formed on the metal. By raising the temp. of the soln., more lead dissolves and some hydrated ferric oxide is precipitated. A soln. of iron-alum, acidified by sulphuric or hydrochloric acid, was found by K. Someya to be completely reduced to ferrous salt by **lead amalgam**. C. L. Berthelot, J. Napier, A. and P. Buisine, and J. J. Berzelius observed that when a soln. of ferric sulphate is digested with **iron** filings, ferrous sulphate is formed, hydrogen is evolved, and a basic ferric sulphate is precipitated. T. E. Thorpe, and J. C. Essner found that, unlike the case with zinc and magnesium, the reducing action is reduced by raising the temp. of the acidified soln. I. A. Lösner observed that iron is scarcely attacked by a sat. soln. of ferric sulphate; A. Hutin utilized the reaction: $\text{Fe}_2(\text{SO}_4)_3 + \text{Fe} = 3\text{FeSO}_4$, in the preparation of green vitriol. J. C. Essner observed that in dil. soln., the rate of reduction of ferric to ferrous sulphate by iron is increased if platinum be present. J. Napier found that the

soln. is reduced by **cobalt**, and by **nickel**, but not by **platinum**. R. Böttger reported that **palladium**, not charged with hydrogen, will reduce a soln. of ferric sulphate to the ferrous state.

A. Vesterberg found that when a conc. soln. of **sodium hydroxide** acts on anhydrous ferric sulphate, a crystalline powder of $\text{Fe}_2\text{O}_3 \cdot \text{H}_2\text{O}$ is formed. A. Krause studied the action of alkali hydroxides and carbonates on soln. of ferric sulphate. E. Kothny found that anhydrous ferric sulphate reacts slowly with **copper oxide** at 300° to 600° , in accord with $3\text{CuO} + \text{Fe}_2(\text{SO}_4)_3 \rightleftharpoons 3\text{CuSO}_4 + \text{Fe}_2\text{O}_3$; between 500° and 550° , the state of equilibrium is such that a third of the total copper is soluble in water. F. Thomas, A. Elliott, and C. Millberg found that copper oxide or **copper hydroxide** dissolves in a soln. of ferric sulphate more rapidly than is the case with cuprous oxide, and, added M. de K. Thompson, if an excess of copper oxide is present, a basic salt is formed. J. D. Sullivan and G. L. Oldright found that acidified soln. of ferric sulphate dissolve particles of **cuprous oxide**, or **cuprite**, of 3's mesh in size in 8 days, and in 3 days 99 per cent. is dissolved. Particles less than 100's mesh dissolve completely in an hour. Oxygen is necessary for complete soln. F. Thomas, and C. Millberg represented the reaction: $3\text{Cu}_2\text{O} + 4\text{Fe}_2(\text{SO}_4)_3 = 6\text{CuSO}_4 + 6\text{FeSO}_4 + \text{Fe}_2\text{O}_3$; and if an excess of sulphuric acid is present, L. L. de Koninck gave $\text{Cu}_2\text{O} + \text{Fe}_2(\text{SO}_4)_3 + \text{H}_2\text{SO}_4 = 2\text{CuSO}_4 + 2\text{FeSO}_4 + \text{H}_2\text{O}$. M. de K. Thompson said that it is probable that the cuprous oxide is first oxidized to cupric oxide before it dissolves. J. A. Hedvall and J. Heuberger observed that anhydrous ferric sulphate begins to react with **calcium oxide** at 584° and the reaction: $3\text{CaO} + \text{Fe}_2(\text{SO}_4)_3 = 3\text{CaSO}_4 + \text{Fe}_2\text{O}_3$ is vigorous at 620° ; the thermal value of the reaction is 61.1 Cals.; the reaction begins with **strontium oxide** at 410° , proceeds vigorously at 510° , and has the thermal value 165.1 Cals.; and the reaction with **barium oxide** begins at 338° , proceeds vigorously at 470° , and has the thermal value 199.2 Cals. D. Balareff discussed the part played by moisture in the reaction. J. A. Hedvall and J. Heuberger found that with barium hydroxide, a reaction occurs slowly at 350° to 395° . G. Keller noted that limonite is formed when **calcite** is treated with soln. of ferric sulphate—*vide supra*, ferrous sulphate. H. Schopper studied the precipitation of ferric hydroxide from soln. of the sulphate by quicklime, or limestone, and J. N. von Fuchs, J. von Kobell, and H. Demarçay observed that the alkaline earths, **magnesium, manganese, zinc, and copper carbonates**, precipitate hydrated ferric oxide from a soln. of ferric sulphate. A. Mailhe found that when **mercuric oxide** is added to a soln. of ferric sulphate, a lemon-yellow powder of $\text{HgSO}_4 \cdot 2\text{HgO}$ is formed; E. A. Schneider also found that with **aluminium hydroxide** at ordinary temp., the iron may all be precipitated as a basic salt, particularly from the boiling soln. C. Fahlberg, L. Lucas, C. Semper and C. Fahlberg, and E. Sack observed that a neutral soln. of ferric sulphate deposits all the iron as hydrated oxide when it is treated with **lead dioxide**. M. K. Hoffmann, and C. Friedheim and M. K. Hoffmann found that **molybdenum dioxide** is oxidized to the trioxide by ferric sulphate soln.: $\text{MoO}_2 + \text{Fe}_2(\text{SO}_4)_3 + \text{H}_2\text{O} = \text{MoO}_3 + 2\text{FeSO}_4 + \text{H}_2\text{SO}_4$. Hydrated ferric oxide is completely precipitated from a soln. of ferric sulphate by **manganese dioxide**, and the reaction was employed by J. W. Kynaston, and P. and F. M. Spence for purifying ferruginous alumina; and by C. Marchal and J. Wiernik, for separating iron from chromium and aluminium. M. Geloso and co-workers, L. S. Lévy, and P. Nicolardot and co-workers studied the adsorption of ferric sulphate soln. by freshly-precipitated manganese dioxide, and the effect of copper and nickel sulphates on the adsorption. G. Kreimer studied the preferential absorption of ferric sulphate from soln. of aluminium sulphate. M. P. Applebey and S. H. Wilkes, F. K. Cameron and W. O. Robinson, A. Maus, S. U. Pickering, R. Scharizer, and F. Wirth and B. Bakke studied the solution of **ferric hydroxide**, and of **ferric oxysulphates** in aq. soln. of ferric sulphate.

The action of **alkali sulphides** on the soln. of ferric sulphate is discussed in connection with the reactions of analytical interest. F. Thomas, and C. Millberg found that **cuprous sulphide** is readily dissolved by a soln. of ferric sulphate:

$\text{Cu}_2\text{S} + 2\text{Fe}_2(\text{SO}_4)_3 = 2\text{CuSO}_4 + 4\text{FeSO}_4 + \text{S}$; and similarly with **cupric sulphide**, $\text{CuS} + \text{Fe}_2(\text{SO}_4)_3 = \text{CuSO}_4 + 2\text{FeSO}_4 + \text{S}$, and the dissolution of cuprous sulphide is favoured by the presence of ferrous sulphate. The thermal value of the above-mentioned reaction with cuprous sulphide was found by S. H. Emmens to be 15.15 Cals. The reaction was studied by J. D. Sullivan, H. E. Keyes, and G. D. van Arsdale. J. Hanus, and P. P. Budnikoff and K. E. Krause added that both reactions are incomplete and probably oxysulphides are formed. L. Whitby found that at ordinary temp. the reaction in acidic soln. can be symbolized: $\text{Cu}_2\text{S} + \text{Fe}_2(\text{SO}_4)_3 = \text{CuS} + \text{CuSO}_4 + 2\text{FeSO}_4$, but with a prolonged action, the reaction follows the course: $\text{CuS} + \text{Fe}_2(\text{SO}_4)_3 = \text{CuSO}_4 + 2\text{FeSO}_4 + \text{S}$. The reaction with an excess of acid, at 60° to 80° , also follows the course of the preceding equation. M. de K. Thompson observed that the action does not occur with cuprous sulphide when air (or oxygen) is excluded. The artificial and natural complex iron and copper sulphides were found by F. Thomas to be very slowly attacked by a soln. of ferric sulphate. P. P. Budnikoff and K. E. Krause represented the quantitative reaction with **calcium sulphide**: $\text{CaS} + \text{Fe}_2(\text{SO}_4)_3 = \text{CaSO}_4 + 2\text{FeSO}_4 + \text{S}$; and S. H. Emmens found that the thermal value of the reaction with **zinc sulphide** is 25.94 Cals. J. Hanus found the analogous reaction with **mercuric sulphide** is incomplete, but the reactions with **stannous sulphide**, and **lead sulphide** are complete. S. H. Emmens gave 14.80 Cals. for the thermal value of the reaction with lead sulphide. G. de Bechi and co-workers utilized the reaction in the treatment of zinc-lead ores. E. Crepaz found that **potassium molybdenum cyanosulphide** is oxidized by ferric sulphate with the separation of sulphur. E. T. Allen and co-workers found that **marcasite** and **pyrite** are attacked by a soln. of ferric sulphate forming ferrous sulphate, sulphuric acid, and sulphur; E. Kothny observed that pyrite is slowly attacked by anhydrous ferric sulphate at 290° , and L. L. de Koninck showed that in a sealed tube with pyrite, and sulphuric acid, at 170° , iron-alum is reduced to ferrous sulphate. S. H. Emmens represented the reaction with **ferrous sulphide**, in aq. soln. of ferric sulphate: $\text{FeS} + \text{Fe}_2(\text{SO}_4)_3 = 3\text{FeSO}_4 + \text{S} + 30.85$ Cals.

According to A. Haswell, and C. Meinecke, the oxidation of **mercurous chloride** by an acid soln. of ferric sulphate: $\text{Hg}_2\text{Cl}_2 + \text{Fe}_2(\text{SO}_4)_3 + 2\text{HCl} = 2\text{HgCl}_2 + 2\text{FeSO}_4 + \text{H}_2\text{SO}_4$, is catalytically favoured by stannic chloride. M. Berthelot discussed the thermal value of admixture of soln. of ferric sulphate with soln. of **sodium, potassium, and ammonium sulphates**. A. Gorgeu found that when anhydrous ferric sulphate is melted with sodium sulphate in a current of dry carbon dioxide, crystalline ferric oxide, ferrosic oxide, iron, iron sulphide, alkali sulphite, and carbon may be produced. The adsorption of ferric sulphate from aq. soln. by precipitated **barium sulphate** was discussed by F. W. Küster and A. Thiel, J. W. Mellor, T. W. Richards and co-workers, and E. A. Schneider. Z. Karaoglanoff observed that barium sulphate is insoluble in a sulphuric acid soln. of ferric sulphate. E. Zintl and F. Schloffer showed that **chromous sulphate** reduces a sulphuric acid soln. of ferric sulphate to the ferrous state. L. C. A. Barreswil found that a soln. of **ferrous sulphate** rapidly dissolves anhydrous ferric sulphate.

§ 46. The Basic Ferric Sulphates

As indicated above, ferric sulphate is readily hydrolyzed, and although a great number of basic salts have been reported, either as laboratory products, or as minerals, less than half a dozen have been prepared under conditions where equilibrium between soln. and solid has been established, and at temp. between 50° and 200°. These basic salts are the heptadecahydrate, $2\text{Fe}_2\text{O}_3 \cdot 5\text{SO}_3 \cdot 17\text{H}_2\text{O}$, the mono- and pentahydrates, $\text{Fe}_2\text{O}_3 \cdot 2\text{SO}_3 \cdot \text{H}_2\text{O}$ and $5\text{H}_2\text{O}$, and the euneahydrate, $3\text{Fe}_2\text{O}_3 \cdot 4\text{SO}_3 \cdot 9\text{H}_2\text{O}$. This work—Figs. 661 to 668—was done by E. Posnjak and H. E. Merwin,¹ F. K. Cameron and W. O. Robinson, M. P. Applebey and S. H. Wilkes, and F. Wirth and B. Bakke. A. Krause, as indicated above, studied the effect of alkalies on soln. of ferric sulphate, and he found that the composition of the precipitate at 15° changes with the OH⁻-ion conc. of the soln. Similar remarks apply to the complex salts of ferric sulphates so that there again basic salts are formed. The following list includes the basic ferric sulphates, and complex basic ferric sulphates which have been reported as minerals:

<i>Amarantite</i> (A. Frenzel, 1890)	$2\text{Fe}_2\text{O}_3 \cdot 2\text{SO}_3 \cdot 7\text{H}_2\text{O}$
<i>Ammoniojarosite</i> (E. V. Shannon, 1929)	$(\text{NH}_4)_2\text{O} \cdot 3\text{Fe}_2\text{O}_3 \cdot 4\text{SO}_3 \cdot 6\text{H}_2\text{O}$
<i>Apatelite</i> (A. Meillet, 1841)	$2\text{Fe}_2\text{O}_3 \cdot 3\text{SO}_3 \cdot 1\frac{1}{2}\text{H}_2\text{O}$
<i>Beaverite</i> (W. T. Schaller, 1912)	$\text{CuO} \cdot \text{PbO} \cdot \text{Fe}_2\text{O}_3 \cdot 2\text{SO}_3 \cdot 4\text{H}_2\text{O}$
<i>Bilinite</i> (J. Sebor, 1903)	$\text{FeO} \cdot \text{Fe}_2\text{O}_3 \cdot 24\text{H}_2\text{O}$
<i>Borgströmite</i> (M. Saxén, 1916)	$\text{Fe}_2\text{O}_3 \cdot \text{SO}_3 \cdot 3\text{H}_2\text{O}$
<i>Botryogen</i> (W. Haidinger, 1828)	$2\text{MgO} \cdot \text{Fe}_2\text{O}_3 \cdot 4\text{SO}_3 \cdot 15\text{H}_2\text{O}$
<i>Butlerite</i> (C. Lausen, 1928)	$\text{Fe}_2\text{O}_3 \cdot 2\text{SO}_3 \cdot 5\text{H}_2\text{O}$
<i>Carphosiderite</i> (A. Breithaupt, 1827)	$3\text{Fe}_2\text{O}_3 \cdot 4\text{SO}_3 \cdot 10\text{H}_2\text{O}$
<i>Castanite</i> (L. Darapsky, 1890)	$\text{Fe}_2\text{O}_3 \cdot 2\text{SO}_3 \cdot 7\text{H}_2\text{O}$
<i>Copiapite</i> (W. Haidinger, 1845)	$2\text{Fe}_2\text{O}_3 \cdot 5\text{SO}_3 \cdot 18\text{H}_2\text{O}$
β - <i>Copiapite</i> (R. Scharizer, 1912)	$3\text{Fe}_2\text{O}_3 \cdot 8\text{SO}_3 \cdot 27\text{H}_2\text{O}$
<i>Clinocrocite</i> (S. Singer, 1879)	(See <i>clinophæite</i>)
<i>Clinophæite</i> (S. Singer, 1879)	$4(\text{K}, \text{Na})_2\text{O} \cdot \text{FeO} \cdot (\text{Fe}, \text{Al})_2\text{O}_3 \cdot 5\text{SO}_3 \cdot 8\text{H}_2\text{O}$
<i>Cubeite</i> (L. Darapsky, 1898)	$3\text{MgO} \cdot 2\text{Fe}_2\text{O}_3 \cdot 7\text{SO}_3 \cdot 3\text{H}_2\text{O}$
<i>Cyprussite</i> (P. F. Reinsch, 1882)	$(\text{Al}, \text{Fe})_2\text{O}_3 \cdot \text{SO}_3 \cdot 6\text{H}_2\text{O}$
<i>Ferronatronite</i> (J. B. Macintosh, 1906)	$3\text{Na}_2\text{O} \cdot \text{Fe}_2\text{O}_3 \cdot 6\text{SO}_3 \cdot 6\text{H}_2\text{O}$
<i>Fibroferrite</i> (H. Rose, 1833)	$\text{Fe}_2\text{O}_3 \cdot 2\text{SO}_3 \cdot 10\text{H}_2\text{O}$
<i>Guildite</i> (C. Lausen, 1928)	$3(\text{Cu}, \text{Fe})\text{O} \cdot 2(\text{Fe}, \text{Al})_2\text{O}_3 \cdot 7\text{SO}_3 \cdot 17\text{H}_2\text{O}$
<i>Glockerite</i> (J. J. Berzelius, 1826)	$2\text{Fe}_2\text{O}_3 \cdot \text{SO}_3 \cdot 6\text{H}_2\text{O}$
<i>Hydroglockerite</i> (E. Greenley, 1919)	$2\text{Fe}_2\text{O}_3 \cdot \text{SO}_3 \cdot 8\text{H}_2\text{O}$
<i>Idrizite</i> (A. Schrauf, 1891)	$(\text{Mg}, \text{Fe})\text{O} \cdot (\text{Al}, \text{Fe})_2\text{O}_3 \cdot 3\text{SO}_3 \cdot 16\text{H}_2\text{O}$
<i>Jarosite</i> (A. Breithaupt, 1852)	$\text{K}_2\text{O} \cdot 3\text{Fe}_2\text{O}_3 \cdot 4\text{SO}_3 \cdot 6\text{H}_2\text{O}$
<i>Louderbackite</i> (C. Lausen, 1928)	$2\text{FeO} \cdot 3(\text{Fe}, \text{Al})_2\text{O}_3 \cdot 10\text{SO}_3 \cdot 15\text{H}_2\text{O}$
<i>Metavoltine</i> (J. Blaas, 1883)	$5(\text{K}_2, \text{Na}_2, \text{Fe})\text{O} \cdot 3\text{Fe}_2\text{O}_3 \cdot 20\text{SO}_3 \cdot 18\text{H}_2\text{O}$
<i>Paposite</i> (L. Darapsky, 1887)	$2\text{Fe}_2\text{O}_3 \cdot 3\text{SO}_3 \cdot 10\text{H}_2\text{O}$
<i>Pastreite</i> (L. Bergemann, 1866)	(See <i>raimondite</i>)
<i>Plagiocitrite</i> (S. Singer, 1879)	$(\text{K}, \text{Na})_2\text{O} \cdot 2\text{FeO} \cdot 3(\text{Al}, \text{Fe})_2\text{O}_3 \cdot 6\text{SO}_3 \cdot 27\text{H}_2\text{O}$
<i>Planoferrite</i> (F. Grünling, 1898)	$\text{Fe}_2\text{O}_3 \cdot \text{SO}_3 \cdot 15\text{H}_2\text{O}$
<i>Quetenite</i> (A. Frenzel, 1890)	$\text{MgO} \cdot \text{Fe}_2\text{O}_3 \cdot 3\text{SO}_3 \cdot 13\text{H}_2\text{O}$
<i>Raimondite</i> (A. Breithaupt, 1866)	$2\text{Fe}_2\text{O}_3 \cdot 3\text{SO}_3 \cdot 7\text{H}_2\text{O}$
<i>Ransomite</i> (C. Lausen, 1928)	$\text{CuO} \cdot \text{Fe}_2\text{O}_3 \cdot 4\text{SO}_3 \cdot 7\text{H}_2\text{O}$
<i>Römerite</i> (J. Grailich, 1858)	$\text{FeO} \cdot \text{Fe}_2\text{O}_3 \cdot 4\text{SO}_3 \cdot 14\text{H}_2\text{O}$
<i>Rubrite</i> (L. Darapsky, 1890)	$\text{Fe}_2\text{O}_3 \cdot 2\text{SO}_3 \cdot 3\text{H}_2\text{O}$
<i>Sideronatronite</i> (A. Raimondi, 1882)	$2\text{Na}_2\text{O} \cdot \text{Fe}_2\text{O}_3 \cdot 4\text{SO}_3 \cdot 7\text{H}_2\text{O}$
<i>Slavikite</i> (R. N. C. R. Jirkorsky and F. Ulrich, 1926)	$(\text{Na}, \text{K})_2\text{O} \cdot 5\text{Fe}_2\text{O}_3 \cdot 13\text{SO}_3 \cdot 66\text{H}_2\text{O}$
<i>Utahite</i> (A. Arzruni, 1884)	$\text{Fe}_2\text{O}_3 \cdot \text{SO}_3 \cdot 2\text{H}_2\text{O}$
<i>Vegasite</i> (A. Knopf, 1913)	$\text{PbO} \cdot 3\text{Fe}_2\text{O}_3 \cdot 4\text{SO}_3 \cdot 6\text{H}_2\text{O}$
<i>Voltaite</i> (J. Blaas, 1883)	$8\text{FeO} \cdot 2\text{K}_2\text{O} \cdot 3(\text{Fe}, \text{Al})_2\text{O}_3 \cdot 20\text{SO}_3 \cdot 46\text{H}_2\text{O}$

A. Recoura reported a product, $7\text{Fe}_2\text{O}_3 \cdot 18\text{SO}_3 \cdot n\text{H}_2\text{O}$, to be formed by the hydrolysis or evaporation of conc. soln. of ferric sulphate, but in all probability

it merely represents an uncompleted stage of the hydrolysis; there is no evidence of it in the equilibrium diagrams.

The yellow earth referred to in the first century as *μῖον* by Dioscorides in his *Περὶ ὕλης ἰατρικῆς*, and as *misy*, by Pliny, in his *Historia naturalis*; and in the sixteenth century as *yellow atrament* by G. Agricola, is thought to refer partly to copiapite and partly to metavoltine. J. D. Dana suggested the term *misylite*, which H. Moissan mis-spells *migsite*. The mineral was described by J. G. Wallerius, J. F. L. Hausmann, A. Breithaupt, and H. Rose. E. F. Glocker called it *xanthosiderite*, and W. Haidinger, **copiapite**—from the locality Tierra Amarilla, near Copiapo, Chili, where the mineral was first found. It has been also reported from other localities—e.g. Knoxville, and Sulphur Bank, California; Rio Tinto, Spain; and Goslar in the Harz. Analyses were reported by G. Linck, C. Lausen, H. F. Collins, C. List, J. B. Macintosh, R. Jirkovsky, L. Darapsky, W. H. Melville and W. Lindgren, I. Domeyko, E. Manasse, W. T. Schaller, R. Scharizer, R. Mauzelius, H. Ahrend, T. L. Walker, W. J. McCaughey, J. F. Schairer and C. C. Lawson, and C. F. Rammelsberg. The results are best represented by the formula: $2\text{Fe}_2\text{O}_3 \cdot 5\text{SO}_3 \cdot 18\text{H}_2\text{O}$, or **ferric oxypentasulphate**, $\text{Fe}_4\text{O}(\text{SO}_4)_5 \cdot 18\text{H}_2\text{O}$ —P. Groth gave $19\text{H}_2\text{O}$; E. Posnjak and H. E. Merwin, $17\text{H}_2\text{O}$; and F. Wirth and B. Bakke, $18\text{H}_2\text{O}$. R. Scharizer's and W. T. Schaller's constitutional formulæ are as follows:

R. Scharizer's formula

W. T. Schaller's formula

R. Scharizer's formula, $(\text{HO} \cdot \text{Fe})_4(\text{SO}_4)_3(\text{HSO}_4)_2 \cdot 15\text{H}_2\text{O}$, is equivalent to a salt formed by the condensation of four mols. of ferrisulphuric acid, $(\text{HO} \cdot \text{Fe})(\text{HSO}_4)_2$, or **ferric hexahydroxypentasulphate**.

Copiapite is the most conspicuous of the basic ferric sulphates; and it is the salt which first separates from an aq. soln. of ferric sulphate, and it can be recrystallized from its aq. soln. without an excess of sulphuric acid being present. R. Scharizer observed that it separates in sulphur-yellow crystals from soln. of ferric sulphate with the mol. ratio $\text{SO}_3 : \text{Fe}_2\text{O}_3$ exceeding 2.5; if the ratio is just 2.5, then copiapite is formed alone; if it is between 2.5 and 3.0, the copiapite is mixed with enneahydrated ferric sulphate; and if the ratio is 3.0, the latter salt is alone produced. F. Wirth and B. Bakke observed that the salt is in equilibrium with a soln. at 25° when the soln. contains Fe_2O_3 , 18.52 to 20.65 per cent., SO_3 , 26.80 to 27.96 per cent., and H_2O , 54.68 to 52.29 per cent. Here the mol. ratio $\text{SO}_3 : \text{Fe}_2\text{O}_3$ is between 2.614 and 2.889. E. Posnjak and H. E. Merwin found that it is stable in contact with its sat. soln. only below 90° —*vide* Figs. 661 to 668.

R. Scharizer prepared what he called β -copiapite corresponding with **ferric hydroxy-tetrasulphate**, $(\text{HO})\text{Fe}_3(\text{SO}_4)_4 \cdot 13\text{H}_2\text{O}$; and F. Wirth and B. Bakke added that it is in equilibrium at 25° with soln. in which the mol. ratio $\text{Fe}_2\text{O}_3 : \text{SO}_3$ lies between 1 : 3.472 and 1 : 2.889. Ordinary copiapite was then called α -copiapite. E. Posnjak and H. E. Merwin have shown that the evidence justifying the recognition of this product as a chemical individual is extremely unsatisfactory, and the only valid inference from the observed results is that equilibrium had not been established, and that the alleged β -copiapite is a mixture of copiapite and normal ferric sulphate. For the identity of *janosite* with copiapite, *vide infra*.

Copiapite occurs in nature as a sulphur-yellow or yellowish-brown incrustation, or in loose aggregates of crystalline scales, or granular masses. G. Linck said that the crystals are monoclinic, with the axial ratios $a : b : c = 0.47904 : 1 : 0.97510$, and $\beta = 72^\circ 3'$, but E. Bertrand, A. des Cloizeaux, Z. Toborffy, and E. Manasse said that the crystals are rhombic. C. Lausen said that the crystals of the copiapite occurring at Jerome, Arizona, are monoclinic. The crystals occur in thin, pseudo-

hexagonal plates parallel to (100). The pinacoid is at (100), the base at (001); they also occur in prisms elongated parallel to (001), and flattened parallel to (010). The (010)-cleavage is perfect, and the (100)-cleavage imperfect. E. Posnjak and H. E. Merwin also found that the pale greenish-yellow, artificial crystals are rhombic with the axial ratios $a:b:c=0.81:1:-$, and added that the crystals have a monoclinic appearance due to the unequal development of the boundaries which correspond with the crystal faces. The crystals of copiapite are usually tabular parallel to (010), and the (010)-cleavage is good. The crystals in the α -direction are colourless; in the β -direction, light greyish-yellow; and in the γ -direction, bright yellow. A. Frenzel said that the green tinge of the crystals is a consequence of their exposure to sunlight, and that it disappears in darkness. The optical character is negative; the optical axial angle $2V=52^\circ$; and, according to A. des Cloizeaux, $2H_0=113^\circ 10\frac{1}{2}'$ for red-light, and $2H_0=114^\circ 15'$ for yellow-light; and G. Linck gave $2H_0=111^\circ 36'$ for yellow-light. G. Linck gave 2.103 for the sp. gr., and C. Lausen, 2.092. The hardness is 2.5. The crystals of copiapite attract moisture, and deliquesce more slowly than either rhomboclase or coquimbite. E. Manasse observed that when copiapite is confined over calcium chloride, it loses about 1.82 per cent. of water, *i.e.* about a mol., and this is thought to be hygroscopic or adsorbed water; R. Scharizer observed further that copiapite loses about 5 mols. of water at 60° ; 6 mols. at 90° , 12 mols. at 116° ; and at a higher temp. 3 more mols. are lost at 200° , and the remaining 2 mols. above 200° . Some results were:

	50°	60°	90°	100°	110°	130°	170°	200°	279°
Loss . . .	1.31	7.98	9.18	14.12	17.31	20.90	24.25	25.98	28.50 per cent.

The dehydration curve has breaks at 60° , 90° , and 120° . There is a marked change in vol. at about 100° when the colour changes from sulphur-yellow to brownish-yellow; it melts in its water of crystallization at 112° . G. Linck's studies on the dehydration are in agreement with those of R. Scharizer. E. Posnjak and H. E. Merwin found that the optical dispersion is small. E. Manasse reported that the indices of refraction of copiapite for Na-light ranged from $\alpha=1.506$ to 1.509, $\beta=1.529$ to 1.532, and $\gamma=1.573$ to 1.577; W. J. McCaughey gave $\alpha=1.525$, $\beta=1.545$, and $\gamma=1.592$; E. S. Larsen, $\alpha=1.510$ to 1.530, $\beta=1.535$ to 1.550, and $\gamma=1.575$ to 1.600; T. L. Walker, $\beta=1.537$, and $\gamma=1.578$; C. Lausen, $\alpha=1.525$, $\beta=1.540$, and $\gamma=1.595$; and W. E. Ford, $\beta=1.53$, and $\gamma=1.57$. E. Posnjak and H. E. Merwin gave for the artificial crystals:

	Fe-	Tl-	Na-	C-	Li-light
α . . .	1.542	1.536	1.531	1.527	1.526
β . . .	1.559	1.552	1.546	1.541	1.540
γ . . .	1.620	1.600	1.597	1.589	1.587

D. Mawson observed that the mineral is readily decomposed by ammonia—liquid, soln., or gas.

According to A. Maus, if a conc. soln. of ferric sulphate be treated with calcium hydroxide or carbonate until the precipitate no longer dissolves, and the liquid be rapidly filtered, the dark brown filtrate contains **ferric oxydisulphate**, with $\text{Fe}_2\text{O}_3:\text{SO}_3=1:2$. The salt is also formed by agitating a conc. soln. of ferric sulphate with the precipitate obtained by treating an excess of ferric sulphate with ammonia in the cold. The yellow deposit formed on crystals of ferrous sulphate on exposure to air also consists of this disulphate, so that a soln. of the altered ferrous sulphate deposits the disulphate when heated. On evaporating the soln. of the disulphate, a gummy yellowish-brown mass is formed; and when the soln. is allowed to stand for some time, disulphate is precipitated whilst the normal sulphate remains in soln. This decomposition is less complete the more conc. the soln.; and for complete decomposition, the soln. must be boiled. The disulphate forms ammonium and potassium salts; and it expels the normal sulphate from its combination with the alkali sulphates. F. Wibel described a sulphur-yellow, crystalline precipitate, corresponding with $\text{Fe}_2\text{O}_3.2\text{SO}_3.2\text{H}_2\text{O}$, said to be formed

by heating a soln. of copper and ferrous sulphates in a closed vessel. The evidence is here too indefinite to establish the existence of these products as chemical individuals.

M. P. Applebey and S. H. Wilkes supposed that an anhydrous basic salt, $7\text{Fe}_2\text{O}_3 \cdot 15\text{SO}_3$, or $5(\text{Fe}_2\text{O}_3 \cdot 3\text{SO}_3) \cdot 2\text{Fe}_2\text{O}_3$, separates at 25° from soln. with between 27 and 30 per cent. SO_3 . The compound is not formed at 18° , and when the acidity is less than 27 per cent. SO_3 at 25° , or 29·6 per cent. at 18° , the solid phases are solid soln. of variable composition. According to G. Keppeler and J. d'Ans, if ferrous sulphate be heated in dry air at about 300° , a chocolate-brown powder is formed of sp. gr. 3·83, and in composition it approximates to anhydrous ferric oxy-sulphate. H. O. Hofman and W. Wanjukoff also observed that the oxydisulphate begins to form at 167° when heptahydrated ferrous sulphate is heated in air; and the reaction is completed at 455° ; at a higher temp., 492° to 560° , it begins to form red ferric oxide. The compound was similarly made by E. Kothny.

E. Posnjak and H. E. Merwin prepared the *monohydrate* of ferric oxydisulphate, $\text{Fe}_2\text{O}_3 \cdot 2\text{SO}_3 \cdot \text{H}_2\text{O}$, may be $\text{Fe}(\text{OH})\text{SO}_4$, under the conditions indicated in Figs. 661 to 668. It is formed above 75° in the system $\text{Fe}_2\text{O}_3 - \text{SO}_3 - \text{H}_2\text{O}$, when the percentage proportions of these three components are 14·31 to 19·74 : 22·71 to 30·80 : 62·98 to 49·46 at 110° ; 12·05 to 15·35 : 22·39 to 30·88 : 65·66 to 53·77 at 140° ; and 0·63 to 1·91 : 5·58 to 48·94 : 93·79 to 49·15 at 200° . The crystals are very pale orange-yellow, with pleochroism α and β colourless, and γ clear yellow. The rhombic crystals appear as fibrous crusts, and rough prisms. The indices of refraction are :

	F-	Tl-	Na-	C-	Li-light
α . . .	1·814	1·796	1·783	1·772	1·770
β . . .	1·844	1·821	1·804	1·790	1·788
γ . . .	1·968	1·940	1·918	1·897	1·894

L. Darapsky described a red mineral from Rio Loa, Chili, and he called it **rubrite**—in allusion to its red colour. When an allowance is made for the gypsum and epsomite present as impurities, its composition corresponds with the *trihydrate* of ferric oxydisulphate, $\text{Fe}_2\text{O}_3 \cdot 2\text{SO}_3 \cdot 3\text{H}_2\text{O}$, or $\text{Fe}(\text{OH})\text{SO}_4 \cdot \text{H}_2\text{O}$. No place has been found for the trihydrate on the equilibrium diagrams, Figs. 661 to 668. C. Lausen found deep orange-yellow crystals of what he called **butlerite**—after G. M. Butler—as a product of the burning of pyrite ore in a mine at Jerome, Arizona. Analyses correspond with the *pentahydrate* of ferric oxydisulphate, $\text{Fe}_2\text{O}_3 \cdot 2\text{SO}_3 \cdot 5\text{H}_2\text{O}$, or $\text{Fe}(\text{OH})\text{SO}_4 \cdot 2\text{H}_2\text{O}$. E. Posnjak and H. E. Merwin prepared the pentahydrate under the conditions indicated in Figs. 661 to 668. The salt is stable below 100° , and, taking percentage proportions of $\text{Fe}_2\text{O}_3 : \text{SO}_3 : \text{H}_2\text{O}$, the salt is stable at 75° when these are 17·78 to 20·93 : 23·10 to 30·11 : 59·12 to 48·96; and at 50° , when they are 17·96 to 21·0 : 22·96 to 28·2 : 59·08 to 50·8. The monoclinic crystals have the axial ratios $a : b : c = 0·858 : 1 : 1·358$, and $\beta = 71^\circ 24'$. C. Lausen said that the crystals of butlerite are rhombic with the axial ratios $a : b : c = 0·9005 : 1 : 1·3606$. The crystals were said to be optically negative, and to have a moderately high birefringence. E. Posnjak and H. E. Merwin said that the diamond-shaped, microscopic, monoclinic crystals have a transverse zone of twinning, with twinning planes normal to the symmetry plane. The basal cleavage is good; and C. Lausen said that one direction of the cleavage parallel to the b pinacoid is good, but the other direction of the cleavage, also pinacoidal, is imperfect. Butlerite is slightly pleochroic, being pale brownish-yellow in the α -direction, and pale canary-yellow in the γ -direction. E. Posnjak and H. E. Merwin said that α is colourless; β , faint yellow; and γ , light yellow. C. Lausen found the sp. gr. of butlerite to be 2·548; the hardness 2·5; and the indices of refraction $\alpha = 1·604$, $\beta = 1·674$, and $\gamma = 1·731$. E. Posnjak and H. E. Merwin gave for the indices of refraction of the pentahydrate :

	F-	Tl-	Na-	C-	Li-light
α . . .	1·603	1·594	1·588	1·581	1·580
β . . .	1·702	1·688	1·678	1·669	1·667
γ . . .	1·782	1·765	1·749	1·735	1·733

A. Frenzel described a mineral from Carracoles, Chili, which he called **amarantite**—from the flower amaranth—in allusion to its colour; a slightly altered form was called **hohmannite**—after T. Hohmann; and a variety from Sierra Gorda was called **paposite**, by L. Darapsky. A. Frenzel, however, showed that paposite, hohmannite, and amarantite belong to the same mineral species. Analyses reported by L. Darapsky, A. Frenzel, J. B. Macintosh, R. Scharizer, F. A. Genth, and M. Gräbner correspond with the *heptahydrate* of ferric oxydisulphate, $\text{Fe}_2\text{O}_3 \cdot 2\text{SO}_3 \cdot 7\text{H}_2\text{O}$. E. A. Wülfing found that no water is lost when amarantite is heated between 40° and 50° ; and R. Scharizer observed a loss of 11.29 per cent. when amarantite is confined over conc. sulphuric acid, and when heated to:

	75°	100°	150°	200°	250°	300°	$>300^\circ$
Loss . . .	11.61	12.30	17.82	23.46	25.76	26.91	28.22 per cent.

The dehydration curve from R. Scharizer's data shows two breaks approximately at 100° and at 200° corresponding with losses of 3 and 6 mols. respectively. A. Frenzel, F. A. Genth, and L. Darapsky found that 12.3 per cent., or 3 mols. of water are lost at 100° . R. Scharizer accordingly represented the formula of the heptahydrate, $\text{Fe}_2\text{O}_3 \cdot 2\text{SO}_3 \cdot 7\text{H}_2\text{O}$, by $(\text{HO} \cdot \text{Fe})_2(\text{SO}_4)_2 \cdot 6\text{H}_2\text{O}$, or $\text{HO} \cdot \text{Fe} : \text{SO}_4 \cdot 3\text{H}_2\text{O}$. Amarantite is orange-yellow at 150° , and brownish-red at 200° . Amarantite usually occurs in columnar, bladed, or radiating masses, or in slender prismatic crystals with the (100)- and (010)-faces vertically striated. The colour is orange-red, brownish-red, or amaranth-red. The pleochroism on α is stronger than on β , which is brownish-red or lemon-yellow. The streak is lemon-yellow. The optical measurements of S. L. Penfield, in agreement with those of E. A. Wülfing, show that the triclinic crystals have the axial ratios $a : b : c = 0.76915 : 1 : 0.57383$, and $\alpha = 95^\circ 38' 15''$, $\beta = 90^\circ 23' 32''$, and $\gamma = 97^\circ 13' 4''$. The (100)-, and (010)-cleavages are perfect. The optical character is negative; and the optic axial angles $2E = 59^\circ 3'$ for Li-light, and $2E = 63^\circ 3'$ for Na-light. The sp. gr. is 2.11, according to A. Frenzel, whilst S. L. Penfield gave 2.286; the hardness is 2.5.

L. Darapsky described a chestnut-brown mineral from Sierra Gorda, Chili, which he called **castanite**—from *castanea*, a chestnut, in allusion to the colour. A. F. Rogers described specimens from Knoxville, California. According to L. Darapsky, and A. F. Rogers, the analysis corresponds with the *octohydrate*, $\text{Fe}_2\text{S}_2\text{O}_9 \cdot 8\text{H}_2\text{O}$. The mineral occurs in prismatic crystals more or less dull and rounded, and united in massive aggregates, or in minute crystals lining cavities. The crystals are monoclinic with a prismatic angle of 82° . According to A. F. Rogers, the prismatic crystals are triclinic with the axial ratios $a : b : c = 0.726 : 1 : 0.895$, and $\alpha = 89^\circ 50'$, $\beta = 91^\circ 10'$, and $\gamma = 78^\circ 46'$. The cleavage parallel to (010) is perfect, and those parallel to (110) and to $(\bar{1}\bar{1}0)$ are less well developed. According to L. Darapsky, the streak is orange-yellow; the sp. gr. 2.118; and the hardness, 3. A. F. Rogers gave 2.2 for the sp. gr., and he found that the indices of refraction are $\alpha = 1.553$, $\beta = 1.643$, and $\gamma = 1.657$, and $\gamma - \alpha = 0.104$. M. C. Bandy gave the hardness 2.5, and $\alpha = 1.550$, $\beta = 1.645$, and $\gamma = 1.660$. According to L. Darapsky, when castanite is heated, it loses water:

	50°	80°	100°	145°	170°	$>170^\circ$
Loss . . .	1.0	9.5	11.8	15.5	20.5	10.2 per cent.

The general behaviour thus resembles that of amarantite, but the loss with amarantite over 200° is 1 mol., and with castanite, 2 mols. A. F. Rogers reported a break in the dehydration curve at 27° . The constitutional formula given by R. Scharizer is:

Castanite is only slightly soluble in water; but it dissolves in warm hydrochloric acid, but in the cold the attack is slow. It remains unchanged in air, and in a desiccator over calcium chloride. A specimen exposed to sunlight crumbled to powder.

H. Rose described a pale yellow or white mineral from Tierra Amarilla, Chili, and a similar mineral has been reported from Paillières, Dept. du Gard; Cetine, Tuscany; Cape Calamita, Elba; and from Red Cliff, California. It was called **fibroferrite** by J. Prideaux; *stypticite*, by J. F. L. Hausmann; and *copiapite*, by J. L. Smith. Analyses by J. L. Smith, T. L. Walker, E. Tobler, F. Field, A. Brun, G. Linck, L. Darapsky, F. Pisani, I. Domeyko, R. Scharizer, E. Manasse, R. A. A. Johnston, H. Rose, and J. Prideaux correspond generally with the *decahydrate*, $\text{Fe}_2\text{S}_2\text{O}_9 \cdot 10\text{H}_2\text{O}$, although in some cases $11\text{H}_2\text{O}$ is nearer the mark. R. Scharizer found the loss on heating to be:

	50°	60°	70°	85°	100°	160°	175°	192°	>192°
Loss . . .	12.17	15.00	19.38	24.40	25.63	28.00	33.01	33.19	36.93

Observations were made by G. Linck, and E. Manasse. The results are taken to correspond with the formula: $(\text{HO} \cdot \text{Fe})_2(\text{SO}_4)_2 \cdot 9\text{H}_2\text{O}$, i.e. $\text{HO} \cdot \text{Fe} : \text{SO}_4 \cdot 4\frac{1}{2}\text{H}_2\text{O}$, or $\text{HO} \cdot \text{Fe} : \text{SO}_4 \cdot 5\text{H}_2\text{O}$. Fibroferrite occurs in delicately fibrous aggregates thought by G. Linck to be monoclinic. The pleochroism is marked— α and β are colourless, and γ is amber-yellow. The optical character is positive. E. Manasse gave for the indices of refraction $\alpha=1.568$, and $\gamma=1.530$; E. S. Larsen, $\alpha=1.525$ to 1.533 , $\beta=1.534$, and $\gamma=1.565$ to 1.575 ; and T. L. Walker, $\alpha=1.518$, $\beta=1.518$, and $\gamma=1.561$. J. L. Smith gave 1.84 for the sp. gr.; and G. Linck, 1.857. The hardness is 2.0 to 2.5.

H. Moissan mentioned the *dodecahydrate*, $2\text{Fe}_2\text{O}_3 \cdot 5\text{SO}_3 \cdot 12\text{H}_2\text{O}$, as occurring in nature in the form of the mineral mysite. O. Meister observed that an iron-pickling acid deposited hyacinth-red, monoclinic crystals of the *pentadecahydrate* of ferric oxydisulphate, $\text{Fe}_2\text{O}_3 \cdot 2\text{SO}_3 \cdot 15\text{H}_2\text{O}$. The crystals effloresce in air; when heated, they melt in their water of crystallization, and lose 35 to 36 per cent. of water; they are sparingly soluble in water; and are decomposed by water, especially if heated.

A. Breithaupt described a mineral from the tin-mines of Ehrenfriedersdorf, and Bolivia, which he called **raimondite**—after A. Raimondi. The analysis corresponds with the empirical formula: $2\text{Fe}_2\text{O}_3 \cdot 3\text{SO}_3 \cdot 7\text{H}_2\text{O}$, or **ferric trioxytrisulphate**. M. Berthelot obtained anhydrous $2\text{Fe}_2\text{O}_3 \cdot 3\text{SO}_3$ by calcining the sulphate. G. C. Wittstein, and F. Muck reported an octohydrate to be formed by oxidizing a soln. of ferrous sulphate in air. A. Mailhe also obtained a hydrate $2\text{Fe}_2\text{O}_3 \cdot 3\text{SO}_3 \cdot n\text{H}_2\text{O}$ by the prolonged action of mercuric oxide on a soln. of ferrous sulphate. The *heptahydrate* raimondite occurs in thin, six-sided tables with replaced basal edges, and also in scale-like crystals which are hexagonal or trigonal. The colour is honey-yellow or ochre-yellow. The basal cleavage is perfect. A. des Cloizeaux said that the crystals are uniaxial and the optical character is negative. E. S. Larsen gave $\omega=1.82$ to 1.867 , and $\epsilon=1.79$. W. T. Schaller, and E. S. Larsen regard raimondite to be really jarosite. A. Meillet found yellow, friable nodules in the clay beds of Meudon, and Auteuil. The analysis corresponded very nearly with the *hemihydrate*, $2\text{Fe}_2\text{O}_3 \cdot 3\text{SO}_3 \cdot 1\frac{1}{2}\text{H}_2\text{O}$, and he called it **apatelite**. W. T. Schaller regards apatelite as one with jarosite. J. D. Dana found that the mineral named **pastreite**—after M. Pastré—by L. Bergemann is related to raimondite; and W. T. Schaller, J. D. Dana, and L. Azéma suggested that pastreite was impure jarosite. Pastreite occurs in yellow, amorphous, reniform masses at Paillières, Dept. du Gard. L. Darapsky described a mineral from Paposa, Atacama, and he called it **paposite**. The dark red mineral occurs in crystals, and in fibrous radiating masses. The analysis approximates $2\text{Fe}_2\text{O}_3 \cdot 3\text{SO}_3 \cdot 10\text{H}_2\text{O}$.

N. Athanasesco heated a 25 per cent. soln. of ferric sulphate at 150° and obtained pale yellow rhombohedra of **ferric pentoxytritetrasulphate**, $3\text{Fe}_2\text{O}_3 \cdot 4\text{SO}_3 \cdot 9\text{H}_2\text{O}$;

if a 3 per cent. soln. be used, the product approximates $10\text{Fe}_2\text{O}_3 \cdot \text{SO}_3 \cdot \text{H}_2\text{O}$, and it was thought to be a mixture. E. Posnjak and H. E. Merwin also obtained the *enneahydrate* with the same composition under the conditions indicated in Figs. 661 to 668; it is stable in contact with soln. up to about 170° . The salt was found to be stable with the proportions by weight, $\text{Fe}_2\text{O}_3 : \text{SO}_3 : \text{H}_2\text{O} = 1.44$ to $17.96 : 2.30$ to 22.96 ; 96.26 to 59.08 at 50° ; 0.93 to $17.98 : 1.62$ to $23.10 : 97.45$ to 59.12 at 75° ; 0.08 to $14.31 : 0.83$ to $22.71 : 99.09$ to 62.96 at 110° ; and 0.8 to $11.5 : 3.5$ to $19.0 : 95.7$ to 69.5 at 140° . It is readily obtained above 75° . G. Tunell and E. Posnjak studied the X-radiograms. E. Posnjak and H. E. Merwin found that the orange-yellow, rhombohedral crystals have the axial ratio $a : c = 1 : 1.14$, and they appear in rhombs with deep bases; and the rhombs are nearly cubes. The pleochroism ω is deep yellow, and ϵ light yellow. The powder appears orange-yellow. The indices of refraction are:

	F-	Tl-	Na-	C-	Li-light
ω . . .	1.865	1.836	1.816	1.799	1.797
ϵ . . .	1.755	1.739	1.728	1.728	1.716

M. Saxén reported a yellow, earthy product of the weathering of the pyrites at Otravaara, Finland, and he named it **borgströmite**—after J. L. H. Borgström. The analysis approximates $\text{Fe}_2\text{O}_3 \cdot \text{SO}_3 \cdot 3\text{H}_2\text{O}$, but later observations indicate that its formula is more likely to be **ferric pentoxytetrasulphate**, $3\text{Fe}_2\text{O}_3 \cdot 4\text{SO}_3 \cdot 9\text{H}_2\text{O}$, and this is in agreement with the observations of E. Posnjak and H. E. Merwin.

A. Breithaupt described a mineral occurring in the fissures in mica-slate in Labrador; J. D. Dana, and F. Pisani said Greenland. It also occurs at St. Léger, near Mâcon, Chihuahua, Mexico, and was called **carphosiderite**—from *κάρφος*, straw; and *σίδηρος*, iron. Analyses reported by E. Wittich, A. Lacroix, and F. Pisani approximate the *decahydrate*, $3\text{Fe}_2\text{O}_3 \cdot 4\text{SO}_3 \cdot 10\text{H}_2\text{O}$. W. T. Schaller represents it by a formula of the utahite type, $[\text{Fe}(\text{OH})_2]_2\text{SO}_4$, namely, $\text{H}_2[\text{Fe}(\text{OH})_2]_6(\text{SO}_4)_4$ —*vide infra*, jarosite. The colour is pale yellow, or deep straw; and the streak is yellowish. The mineral occurs in reniform masses and incrustations, and also in lamellæ. The crystals are uniaxial and possibly rhombohedral; the cleavage is basal; the optical character is positive; and the birefringence is strong. A. Breithaupt gave 2.49 to 2.50 for the sp. gr., and F. Pisani, 2.728. The hardness is 4.0 to 4.5.

E. Soubeiran added potassium carbonate to a soln. of ferric sulphate so long as the alkali does not produce a permanent turbidity, and heated the red liquid until a precipitate is formed. The light reddish-yellow powder had a composition corresponding with the *trihydrate* of **ferric dioxysulphate**, $\text{Fe}_2\text{O}_3 \cdot \text{SO}_3 \cdot 3\text{H}_2\text{O}$. A. Arzruni described an orange-yellow incrustation on the quartz in the Tintic district, Utah, and he called the mineral **utahite**. Analyses by A. Damour, and K. Thaddeëff approximate to the *dihydrate*, $\text{Fe}_2\text{O}_3 \cdot \text{SO}_3 \cdot 2\text{H}_2\text{O}$. The constitutional formula may be, as suggested by K. Thaddeëff, $[(\text{HO})_2\text{Fe}-\text{SO}_4-\text{Fe}(\text{OH})_2]$; R. Scharizer gave $[\text{Fe}(\text{OH})_2]_6[\text{SO}_4]_3$; and S. L. Penfield, $[(\text{HO})_2\text{Fe}]_8[\text{SO}_4]_{14}$. Utahite occurs in aggregates of fine scales consisting of tabular hexagonal crystals with rhombohedral faces. A. Arzruni gave for the axial ratio of the rhombohedral crystals $a : c = 1 : 1.0576$. The optical character is negative, and the crystals are often optically anomalous. The pleochroism is strong—pale yellow and yellowish-brown. The index of refraction given by E. S. Larsen is $\omega = 1.82$. W. T. Schaller considered utahite to be the same mineral species as jarosite. The mineral is said to be insoluble in water and nitric acid.

L. Darapsky reported a mineral in the Lautaro mine, Morro Moreno, Atacama, which he called **planoferrite**. Analyses correspond with the *pentadecahydrate*, $\text{Fe}_2\text{O}_3 \cdot \text{SO}_3 \cdot 15\text{H}_2\text{O}$. The mineral was also described by F. Grünling. The colour is yellowish-green to brown, and the streak is chrome-yellow. The hexagonal plates are probably rhombic, and they have a basal cleavage, and faces on the edges. The hardness is 3.

P. F. Reinsch described sulphur-yellow, soft, chalk-like aggregates of microscopic crystals found in the dolerite of Chrysophone, Cyprus; and he called it *cyprusite*. According to H. Fulton, the analysis approximates $\text{Al}_2(\text{SO}_4)_3 \cdot 8\text{Fe}_2(\text{SO}_4)_3 \cdot 18\text{H}_2\text{O}$, when deductions are made for impurities. R. Scharizer added that the formula may be that of the *hexahydrate*, $\text{R}_2\text{O}_3 \cdot \text{SO}_3 \cdot 6\text{H}_2\text{O}$. The six-sided plates are probably hexagonal; and the optical character is negative. E. S. Larsen gave for the indices of refraction $\omega = 1.803$ and $\epsilon = 1.72$. W. T. Schaller regarded *cyprusite*, as well as *utahite*, *carphosiderite*, *apatelite*, *raimondite*, and *pastreite* as crystallographically equivalent to *jarosite*.

According to J. J. Berzelius, if a soln. of ferric sulphate be treated with insufficient ammonia for complete decomposition, or if an aq. soln. of ferrous sulphate is exposed to the air, **ferric pentoxysulphate**, $2\text{Fe}_2\text{O}_3 \cdot \text{SO}_3 \cdot 6\text{H}_2\text{O}$, is formed. It is also deposited in vitriol and alum works by the action of air on the mother-liquors. C. Weltzien said that the same compound is formed when a soln. of ferrous sulphate is treated with hydrogen dioxide. The analyses of G. C. Wittstein, and F. Muck show that the composition of the precipitate varies with the conditions. S. U. Pickering regarded $2\text{Fe}_2\text{O}_3 \cdot \text{SO}_3 \cdot n\text{H}_2\text{O}$, or, as he wrote it, $\text{Fe}_2(\text{SO}_4)_3 \cdot 5\text{Fe}_2\text{O}_3$, as the only basic salt capable of existence as a chemical individual. W. N. Rae also found that the white precipitate deposited on keeping soln. of ammonium ferric alum, has the composition $2\text{Fe}_2\text{O}_3 \cdot \text{SO}_3 \cdot n\text{H}_2\text{O}$. C. Weltzien represented it as the *octohydrate*; O. Meister, as the *heptahydrate*; and J. J. Berzelius, and F. Muck as the hexahydrate, which they obtained by oxidizing a soln. of ferrous sulphate with hydrogen dioxide. F. Cornu believed that *glockerite*, $2\text{Fe}_2\text{O}_3 \cdot \text{SO}_3 \cdot 6\text{H}_2\text{O}$, is an adsorption compound of hydrated ferric oxide.

J. J. Berzelius said that the *hexahydrate* occurs in nature in the form of what he called *Vitriolocker*, or *vitriol ochre*, which F. S. Beudant called *pittizite*—a name applied to a hydrated ferric sulphatoarsenate. C. F. Naumann employed the term **glockerite**—after E. F. Glocker. Analyses, reported by J. J. Berzelius, F. Hochstetter, L. A. Jordan, T. Scheerer, J. Eyerma, A. H. Church, and J. Thiel, agree with the hexahydrate formula. Vitriol ochre is coloured brown to ochre-yellow, dull green, and brownish-black to pitch-black; and it may be earthy, massive, or stalactitic. A. Breithaupt and O. L. Erdmann also described a vitriol ochre from the alum-shale quarry at Grunsdorf which had a sp. gr. 1.8, and was rather more hydrated than *glockerite*; and E. Greenly called a similar specimen, an *octohydrate*, $2\text{Fe}_2\text{O}_3 \cdot 2\text{SO}_3 \cdot 8\text{H}_2\text{O}$, from Parys Mountain, Anglesey, **hydroglockerite**.

Other products have been analyzed. T. Scheerer found that that obtained by boiling a dil. soln. of ferric sulphate approximates $3\text{Fe}_2\text{O}_3 \cdot \text{SO}_3 \cdot 4\text{H}_2\text{O}$; E. F. Anthon, by precipitating a soln. of ferric sulphate with barium acetate, and adding baryta-water to the filtrate, obtained $4\text{Fe}_2\text{O}_3 \cdot \text{SO}_3 \cdot n\text{H}_2\text{O}$; and T. Scheerer, obtained a product corresponding with $7\text{Fe}_2\text{O}_3 \cdot \text{SO}_3 \cdot 10.5\text{H}_2\text{O}$ or $6\text{Fe}_2\text{O}_3 \cdot \text{SO}_3 \cdot 10\text{H}_2\text{O}$, by the weathering of iron pyrites in alum shale. N. Athanasesco obtained what he regarded as $10\text{Fe}_2\text{O}_3 \cdot \text{SO}_3 \cdot \text{H}_2\text{O}$, by heating a 3 to 4 per cent. soln. of ferric sulphate in a sealed tube at 275° . The crystals of the dark brown powder are not well-defined.

§ 47. Complex Salts with Ferric Sulphate

M. Lachaud and C. Lepière¹ prepared ammonium ferric trisulphate, $3(\text{NH}_4)_2\text{SO}_4 \cdot \text{Fe}_2(\text{SO}_4)_3$, or $(\text{NH}_4)_3\text{Fe}(\text{SO}_4)_3$, by dissolving ferrous or ferrous ammonium sulphate in a fused ammonium sulphate, washing out the excess of ammonium sulphate from the cold mass with alcohol, and again heating the product with ammonium sulphate. The white, prismatic needles have a sp. gr. of 2.31 at 14°. If the heating be prolonged, ammonium ferric disulphate, $(\text{NH}_4)_2\text{SO}_4 \cdot \text{Fe}_2(\text{SO}_4)_3$, or $\text{NH}_4\text{Fe}(\text{SO}_4)_2$, crystallizing in hexagons, is formed. R. F. Weinland and F. Ensgraber obtained a similar salt, as a white crystalline powder, by heating a soln. of ammonium ferric alum with sulphuric acid for some hours. M. Lachaud and C. Lepière found that the sp. gr. is 2.45 at 14°; and O. Pettersson gave 2.54 at 16.8°. The salt is sparingly soluble in water. R. F. Weinland and F. Ensgraber regard it as a salt of ferridisulphuric

acid, $\text{H}[\text{Fe}(\text{SO}_4)_2]$. J. J. Berzelius, G. Forchhammer, and E. Mitscherlich obtained crystals of the *dodecahydrate*, or *ammonium ferric alum*, $(\text{NH}_4)_2\text{SO}_4 \cdot \text{Fe}_2(\text{SO}_4)_3 \cdot 24\text{H}_2\text{O}$, by crystallization from a mixed soln. of the component salts. If the crystals have a yellow tinge, this is due to the presence of an excess of the ferric salt and it disappears when the salt is re-crystallized. M. L. Negri and A. A. Bado described manufacturing this alum on a large scale for the purification of water. J. L. Howe and E. A. O'Neal obtained the salt by the electrolysis of a soln. of ammonium and ferrous sulphates acidified with sulphuric acid; the cathode is a platinum wire dipping in an acidified soln. of ferrous sulphate contained in a porous pot which is placed in the soln. of mixed sulphates. A current of 0.04 amp. is passed through the cell, and in a few hours, crystals of the alum are deposited round the anode.

The crystals are colourless octahedra and cubo-octahedra belonging to the cubic system, and they are isomorphous with the other members of the alum family. They were studied by Z. Weyberg. According to J. Bonnell and E. P. Perman, the violet colour is not due to the presence of a manganese salt as suggested by W. Ostwald, but the pure salt is violet, and the colourless salt is due to the masking of the violet by the complementary yellowish-brown of colloidal ferric hydroxide. L. Vegard and E. Esp examined the X-radiograms, and it was inferred that there are six atoms of oxygen from the water next to the univalent metal, then the sulphate group with a base of the tetrahedron towards the water group, and the point directed towards the trivalent metal. The whole forms a compact unit along the trigonal axis, which is terminated at each end by a metallic atom. L. Vegard and A. Maurstad found the X-radiogram of the anhydrous salt, $\text{NH}_4\text{Fe}(\text{SO}_4)_2$, corresponded with a hexagonal space-lattice having $a=4.825 \text{ \AA}$., and $c=8.310 \text{ \AA}$., and a mol. of the salt per unit cell. According to A. Knop, when the crystals are placed in the corresponding aluminium salt, they are transformed into pseudomorphs of the latter salt. F. Klocke found crystals optically anomalous. H. Kopp gave 1.712 for the sp. gr.; L. Playfair and J. P. Joule, 1.718; H. Topsøe and C. Christiansen, 1.719; H. G. F. Schröder, 1.700; O. Pettersson, 1.725 at 17° and 1.723 at 18° ; and C. Sorét, 1.713. K. Wendekamm gave for the different iron alums:

	K	Rb	Cs	Tl	NH_4
Specific gravity . . .	1.831	1.952	2.066	2.351	1.719
Mol. volume . . .	274.9	281.6	289.7	284.4	280.5
Index of refraction . .	1.4817	1.4823	1.4838	1.5237	1.4848
Mol. refraction . . .	78.31	80.32	82.81	87.00	80.34

G. T. Gerlach gave for the sp. gr. of aq. soln. at 15° :

$\text{NH}_4\text{Fe}(\text{SO}_4)_2 \cdot 12\text{H}_2\text{O}$.	5	10	15	20	25	30	35	40 per cent.
Specific gravity . . .	1.023	1.047	1.071	1.096	1.122	1.148	1.175	1.20

The 20 per cent. soln. is saturated at this temp. W. N. Rae found the sp. gr. of soln. with 0.0080, 0.0502, 0.1000, and 0.2000 grm. of the hydrate per c.c. to be respectively 0.99849, 1.01670, 1.03801, and 1.0796 at 32.5° , and the corresponding mol. soln. vol. are: 99, 113.7, 116.8, and 124.3. According to W. N. Rae, soln. containing C grms. of hydrated alum per c.c. had the sp. gr.:

C . . .	0.2000	0.15000	0.1000	0.0502	0.0350	0.0250	0.0201	0.0080
Sp. gr. . . .	1.07960	1.05907	1.03801	1.01670	1.01025	1.00592	1.00376	0.99849

E. Wiedemann studied the changes in vol. which occur when the salt is heated. J. Locke observed that the salt melts in its water of crystallization at 40° . S. Lupton found that the crystals of $(\text{NH}_4)_2\text{SO}_4 \cdot \text{Fe}_2(\text{SO}_4)_3 \cdot 24\text{H}_2\text{O}$ lose 23 mols. of water at 150° , and all is lost at 230° . C. Montemartini and E. Vernazza studied the action of heat on the soln. H. C. Jones and E. Mackay measured the lowering of the f.p. of aq. soln., and the results show that the alum exists in the more conc. soln., but in dil. soln. the complex alum molecule is broken down into the simple sulphates which are, in turn, more or less ionized. P. A. Favre and C. A. Valsøen found the

heat of soln. of a mol of the dodecahydrate in 500 mols of water is -16.6 Cals. According to C. Soret, the indices of refraction, μ , are :

	A-	B-	C-	D-	E-	b-	F-	G-
μ . . .	1.47927	1.48029	1.48150	1.48482	1.48921	1.48993	1.49286	1.49980

whilst H. Topsøe and C. Christiansen gave for the C-, D-, and F- lines, respectively 1.4821, 1.4854, and 1.4934—*vide supra*. T. Swensson studied the action of light and observed no photoelectric effect. H. Kauffmann studied the Faraday effect. J. Errera and H. Brasseur studied the sp. induction and the water of crystallization of the alums.

G. Forchhammer observed that 1 part of the salt dissolves in 3 parts of water ; and J. Locke, that 100 c.c. of water at 25° dissolve 44.15 grms. of the anhydrous salt, or 124.4 grms. of the hydrated salt, so that 1.659 mols of the anhydrous salt can dissolve in a litre of water. Aq. soln. of the salt become turbid when diluted, although conc. soln. will remain clear for months. W. N. Rae found that the addition of ammonium sulphate favours the hydrolysis, whilst sulphuric acid acts in the converse way. The hydrolysis is symbolized : $2\text{Fe}_2(\text{SO}_4)_3 + 2(\text{NH}_4)_2\text{SO}_4 + 5\text{H}_2\text{O} \rightleftharpoons 2\text{Fe}_2\text{O}_3.\text{SO}_3 + 5\text{H}_2\text{SO}_4 + 2(\text{NH}_4)_2\text{SO}_4$; or $4\text{Fe}^{+++} + \text{SO}_4^{--} + 5\text{H}_2\text{O} \rightleftharpoons 2\text{Fe}_2\text{O}_3.\text{SO}_3 + 10\text{H}^+$. W. N. Rae found that the change of colour of the soln. which occurs on hydrolysis corresponds with the assumption that the colour is due to the presence of the soluble basic sulphate $2\text{Fe}_2\text{O}_3.\text{SO}_3$. W. N. Rae found the precipitate which separates on keeping the aq. soln. is $\text{Fe}_2\text{O}_3.\text{SO}_3$; the colour of the aq. soln. is in agreement with the assumption that a basic soluble salt is present. The white precipitate produced on adding conc. sulphuric acid to the soln. is the anhydrous alum. H. C. Jones and E. Mackay found that the lowering of the f.p. for 0.257N-, 0.064N-, and 0.0014N-soln. were respectively 1.820° , 0.505° , and 0.066° ; and that the mol. electrical conductivity of soln. with a mol of the salt in v litres of water at 25° was :

v	4	20	40	200
μ	118.9	177.4	211.5	320.2

C. L. Wagner found that the soln. become turbid, deposit a precipitate, and become colourless without the conductivity becoming constant, or attaining, in the case of the corresponding potassium ferric alum, the value required for soln. of sulphuric acid and potassium sulphate containing the eq. of the SO_4 -ions. Thus, for soln. with an eq. of ammonium iron alum in v litres, time t min., the eq. conductivity, λ , was :

t	1	2	80	195*	1225	2568	7202 mins.
$\lambda(v=40)$	86.6	86.6	87.1	87.4	95.8	101.6	107.2

Turbidity begins to develop at the time denoted by the asterisk :

t	1	2	92	1360*	2875	4350	5995 mins.
$\lambda(v=1600)$	249.0	257.9	295.2	302.2	303.5	304.0	305.1

H. C. Jones and E. Mackay found the electrical conductivity of the soln. increased with time. The values of μ for soln. with $v=200$ increased from 320.2 to 330.0 in 2 hrs. ; and for a soln. with $v=2000$, the values of μ were 694.0, 808.2, 891.0, and 896.0 respectively in 0, 0.5, 1.8, and 21 hrs. D. E. Olshevsky studied the orientation of the crystals in a magnetic field. J. Forrest found indications of anisotropy, and of magnetic cubic symmetry with the crystals in magnetic fields of the order of 20,000 gauss. The subject was studied by C. G. Montgomerie. C. L. Wagner assumed that the enormous surface of the dispersed colloid adsorbs the acid ions, and that as coagulation proceeds, and the surface is accordingly diminished, the adsorbed acid returns to the soln.

G. Foex, J. Aharoni and F. Simon, and L. C. Jackson examined the magnetic properties of ammonium ferric sulphate. L. A. Welo's results for the

solid and fused salt are summarized in Fig. 580. T. Ishiwara, and K. Honda and T. Ishiwara gave for $(\text{NH}_4)_2\text{SO}_4 \cdot \text{Fe}_2(\text{SO}_4)_3$:

	-177.0	-86.6°	22.4°	132.7°	279.7°	409.6°
$\chi \times 10^6$	170.3	91.6	59.6	37.5	50.0	41.9

and for $(\text{NH}_4)_2\text{SO}_4 \cdot \text{Fe}_2(\text{SO}_4)_3 \cdot 24\text{H}_2\text{O}$:

	-172.6°	-76.0°	19.0°	129.0°	236.7°	549.2°	931.1°
$\chi \times 10^6$	94.6	46.9	30.6	22.4	18.1	10.8	3.0

H. K. Onnes and E. Oosterhuis found that at $T^\circ \text{K.}$, the mass susceptibility $\chi \times 10^6$, and the product $T\chi \times 10^5$, are:

T	200°	169.6°	77.3°	64.6°	20.4°	17.9°	14.7° K.
$\chi \times 10^6$	30.4	51.8	114.7	137	432	492	598
$T\chi \times 10^5$	882	879	887	885	881	881	879

As indicated above, when sulphuric acid is added to a soln. of ammonium ferric alum, a white precipitate approximating $\text{NH}_4\text{Fe}(\text{SO}_4)_2$ is formed. S. F. Ravitz and R. G. Dickinson studied the photochemical reduction of the salt in the presence of polyiodides; W. Moldenhauer, and E. Mischke, the action of hydrogen sulphide on the salt; M. N. Mittra and N. R. Dhar, the catalytic action of the salt on the oxidation of sulphurous acid; N. Schiloff and B. Nebrassoff, the adsorption of the salt by *schönite*. A. Purgotti represented the reaction with hydrazine by the equation: $5\text{N}_2\text{H}_4 + 4\text{Fe}_2\text{O}_3 = 8\text{FeO} + 4\text{NH}_3 + 3\text{N}_2 + 4\text{H}_2\text{O}$; and M. Bobtelsky and D. Kaplan, the effect of this salt on the decolorization of soln. of potassium permanganate. L. R. W. McCay and W. T. Anderson studied the reducing action of mercury, which is rapid and complete at 60° to 70° ; and Y. Ono, the action of ammonium oxalate.

According to A. Maus, when ammonia is added to a soln. of ammonium ferric alum until the precipitate is no longer dissolved, and the dark brown liquid is allowed to evaporate spontaneously, short, regular, six-sided prisms of the basic salt **ammonium ferric oxytetrasulphate**, $2(\text{NH}_4)_2\text{SO}_4 \cdot \text{Fe}_2\text{O}(\text{SO}_4)_2 \cdot 4\text{H}_2\text{O}$, are formed. One part of the salt is soluble in 2.4 parts of water. J. C. G. de Marignac added that the salt loses half its water in vacuo at ordinary temp., or in air at 100° . Ammonia is evolved at a higher temp. D. E. Olshevsky studied the orientation of the crystals in a magnetic field.

A. Grimm and G. Ramdohr obtained **potassium ferric heptasulphate**, $\text{K}_2\text{SO}_4 \cdot 2\text{Fe}_2(\text{SO}_4)_3$, in white, tabular crystals, as a by-product in the preparation of carbon monoxide from a soln. of 1 part of potassium ferrocyanide and 9 parts of conc. sulphuric acid. A. Étard prepared **potassium ferric trisulphate**, $3\text{K}_2\text{SO}_4 \cdot \text{Fe}_2(\text{SO}_4)_3$, or $\text{K}_3\text{Fe}(\text{SO}_4)_3$, as a white powder insoluble in water, but slowly decomposed by that liquid. R. F. Weinland and F. Ensgraber obtained **potassium ferric disulphate**, $\text{K}_2\text{SO}_4 \cdot \text{Fe}_2(\text{SO}_4)_3$, or $\text{K}[\text{Fe}(\text{SO}_4)_2]$, by heating a soln. of potassium ferric alum for some hours with sulphuric acid. The *dodecahydrate*, $\text{KFe}(\text{SO}_4)_2 \cdot 12\text{H}_2\text{O}$, or *potassium ferric alum*, $\text{K}_2\text{SO}_4 \cdot \text{Fe}_2(\text{SO}_4)_3 \cdot 24\text{H}_2\text{O}$, is formed by allowing a mixture of conc. soln. of potassium and ferric sulphates to stand for some days at 0° . The salt was so prepared by R. Richter, and W. Heintz. The electrolytic process employed for the ammonium salt is not good because of the low solubility of potassium sulphate. W. Heintz noted that the commercial salt is usually contaminated with potassium sulphate. The crystals of potassium ferric alum are octahedra, isomorphous with the other members of the family of alums. R. Hollemann studied this subject. G. Tammann and A. Sworykin studied the solid soln. with potassium alum. W. Richter observed that the crystals become matte on exposure to air. C. Christiansen showed that the purified salt furnishes colourless crystals, and that the violet colour is due to the presence of some manganese alum. H. Topsøe and C. Christiansen gave 1.831 for the sp. gr.; O. Pettersson, 1.819 to 1.831; and C. Soret, 1.806. F. Ephraim and P. Wagner

discussed the mol. vol.—*vide supra*. G. T. Gerlach gave for the sp. gr. of aq. soln. at 15° :

KFe(SO ₄) ₂ .12H ₂ O	5	10	15	20	25	30	35 %
Specific gravity	1.025	1.0507	1.0773	1.1050	1.1340	1.1645	1.1967
	(1.0268)	(1.0466)	(1.0672)	(1.0894)	(1.1136)	(1.1422)	(1.1967)

The values in brackets were determined by B. Franz at 17.5°. J. Beckenkamp found that the elastic modulus perpendicular to the (110)-face is 1862 kgrms. per sq. mm. J. Locke observed that the salt melts in its water of crystallization at 28°. R. Scharizer observed that the loss of water at different temp. is as follows :

	48°	60°	70°	87°	100°	114°	152°
Loss	30.59	36.02	40.10	40.35	41.24	41.41	43.03 per cent.

showing that of the 42.93 per cent. of water contained by potassium ferric alum, K₂SO₄.Fe₂(SO₄)₃.24H₂O, about 40 per cent.—corresponding with 22 mols.—is given off below 70°, and that the last 2 mols. are given off slowly as the temp. rises to 152°. These two mols. of water are supposed to represent constitutional water, the other 22 mols., water of crystallization. W. Richter found that at a red-heat it is decomposed into ferric oxide and potassium sulphate, and sulphur trioxide ; whilst W. Heintz observed that at a lower temp.—between 60° and 100°—the reaction can be symbolized : 10KFe(SO₄)₂=2Fe₂(SO₄)₃+5(K₂O.3Fe₂O₃.12SO₃).+2SO₃. C. Montemartini and E. Vernazza studied the action of heat on the soln. S. Miyamoto studied the reduction of the salt in hydrogen in the electric discharge. E. F. Anthon showed that 1 part of the salt dissolves in 5 parts of water at 12.5°. The salt is insoluble in alcohol. The soln. of potassium ferric alum in a little hot water was observed by W. Richter to deposit a greenish-yellow salt which is afterwards converted into the alum and redissolved. The brown colour of the aq. soln. was attributed by H. Rose to the presence of a basic salt in soln. ; the soln. in dil. sulphuric acid is colourless—*vide supra*, ammonium ferric alum. The hydrolysis of aq. soln. was studied by C. R. C. Tichborne. R. Scharizer showed that potassium ferric alum cannot be re-crystallized from its aq. soln. at room temp. because hydrolysis occurs, metavoltine (*q.v.*) is precipitated, and the soln. becomes more acid. K. Someya studied the reduction of the salt with lead amalgam.

According to W. F. Foshag, the *dihydrate*, K₂SO₄.Fe(SO₄)₃.2H₂O, occurs as a mineral at Borate, San Bernardino Co., California, and he called it **krausite**—after E. H. Kraus. It occurs in aggregates of crystals with a pale mauve colour superposed on the yellow colour of the purer mineral. The prismatic crystals are monoclinic with the axial ratios *a* : *b* : *c* = 1.5401 : 1 : 1.7584, and β = 102° 44'. The basal cleavage is good, and that parallel to the (100)-face is also good. The sp. gr. is 2.840, and the hardness 2.5. The crystals are biaxial, the optical character is positive ; the optic axial angle is very large ; the indices of refraction are α = 1.588, β = 1.650, and γ = 1.722 ; and the birefringence is large. Krausite is insoluble in water ; and is slowly hydrolyzed when left in contact with water. It dissolves slowly and completely in hydrochloric acid.

R. Scharizer observed that when an aq. soln. of potassium ferric alum is allowed to crystallize, metavoltine—*vide infra*—is precipitated, and the soln. becomes acidic ; but if the soln. be evaporated to dryness the metavoltine disappears, and a pale violet salt takes its place. The same salt is obtained when a soln. of the composition of the alum is acidified with sulphuric acid and allowed to crystallize. An analysis of the salt corresponds with K₂Fe₂S₄O₁₆.8H₂O, or the *tetrahydrate*, KFeS₂O₈.4H₂O. The losses which occur when the salt is heated to different temp. are :

	48°	57°	70°	72°	114°	152°
Loss	3.31	4.41	0.04	13.25	19.32	19.64 per cent.

The dehydration curve, Fig. 672, shows thin breaks corresponding with the loss of 3, 6, and 7 mols. of water. This is taken to mean that 2 of the 8 mols. of water are constitutional, so that the formula is H₂K₂[Fe(OH)]₂(SO₄)₄.6H₂O, or more simply, **potassium ferric dihydrodisulphate**,

E. Beutel and A. Kutzelnigg found that exposure to ultra-violet light hastens the dehydration of the salt.

The monoclinic crystals have the axial angles $a : b : c = 0.95016 : 1 : 1.0221$, and $\beta = 72^\circ 43'$. The birefringence is large. The sp. gr. is 2.403. Small crystals are white, but in masses, the colour appears reddish-violet. The salt is readily soluble in water, for 100 parts of water at ordinary temp. dissolve 22 parts of the salt. The salt in dil. soln. is hydrolyzed, and the insoluble end-product of the hydrolysis corresponds with $\text{K}_2\text{Fe}_6\text{S}_5\text{O}_{25}$.

E. Soubeiran added potassium carbonate to a soln. of ferric sulphate until the precipitate no longer redissolved, and mixed the dark brown liquid with alcohol in excess. The light reddish-brown precipitate, after washing with alcohol, corresponded with $2\text{K}_2\text{SO}_4 \cdot 3\text{Fe}_2\text{O}(\text{SO}_4)_2 \cdot 22\text{H}_2\text{O}$. The moist precipitate is soluble in water, but not if it has been dried. The salt is decomposed by water. T. Scheerer triturated potassium iron alum with absolute alcohol, and obtained a yellow powder, $4\text{K}_2\text{O} \cdot 3\text{Fe}_2\text{O}_3 \cdot 12\text{SO}_3 \cdot 24\text{H}_2\text{O}$; by similarly treating a conc., aq. soln. of the alum with absolute alcohol, the brownish-green precipitate, after drying 13 days at 18° , had the composition: $8\text{K}_2\text{O} \cdot 6\text{Fe}_2\text{O}_3 \cdot 24\text{SO}_3 \cdot 39\text{H}_2\text{O}$, and if the precipitate be dried over sulphuric acid in vacuo, he said that the composition is: $3\text{K}_2\text{O} \cdot 2\text{Fe}_2\text{O}_3 \cdot 8\text{SO}_3 \cdot 9\text{H}_2\text{O}$; but if the precipitate when formed be boiled for 1 minute, the composition is $5\text{K}_2\text{O} \cdot 3\text{Fe}_2\text{O}_3 \cdot 12\text{SO}_3 \cdot 12\text{H}_2\text{O}$. There is little doubt that these products represent mixtures produced by the hydrolysis of potassium iron alum.

FIG. 672.—Dehydration Curve of $\text{K}_2\text{Fe}_2\text{S}_4\text{O}_{16} \cdot 8\text{H}_2\text{O}$.

A. Maus observed that if potassium hydroxide be added to a soln. of potassium ferric alum until the precipitate no longer dissolves, and the dark brown liquid be allowed to evaporate spontaneously, yellowish-brown, regular, six-sided prisms shortened into plates are deposited. A similar salt was prepared by E. F. Anthon from a soln. of 78 parts of ferric oxide, 147 parts sulphuric acid, and 87.2 parts of potassium sulphate; and by W. Richter, by adding a boiling soln. of potassium sulphate to a supersaturated soln. of ferric sulphate. R. Scharizer also observed that this salt is formed by the action of a soln. of potassium hydrosulphate on hydrated ferric oxide. The analyses discussed by A. Maus, T. Scheerer, C. F. Rammelsberg, E. F. Anthon, W. Richter, and J. C. G. de Marignac correspond approximately with **potassium ferric dioxydodecasulphate**, $5\text{K}_2\text{O} \cdot 3\text{Fe}_2\text{O}_3 \cdot 12\text{SO}_3 \cdot 18\text{H}_2\text{O}$, or $5\text{K}_2\text{SO}_4 \cdot 2\text{Fe}(\text{SO}_4)_3 \cdot \text{Fe}_2\text{O}_2(\text{SO}_4) \cdot 18\text{H}_2\text{O}$. This compound is sometimes called *Maus' salt*—W. Haidinger called it *mausite*. The crystals were examined by J. C. G. de Marignac, and W. Haidinger noted that they are optically anomalous like tourmaline. A. Maus found that 1 part of the salt dissolves in 6 parts of cold water, and the aq. soln. soon deposits crystals of basic ferric sulphate. E. F. Anthon said that if the salt be treated with hot water there remains a pale yellow powder with the composition: $\text{K}_2\text{O} \cdot 3\text{Fe}_2\text{O}_3 \cdot 10\text{SO}_3 \cdot 18\text{H}_2\text{O}$. T. Scheerer said that if this salt be kept for a long time in a warm, dry place, the efflorescence has the composition: $10\text{K}_2\text{O} \cdot 6\text{Fe}_2\text{O}_3 \cdot 24\text{SO}_3 \cdot 33\text{H}_2\text{O}$.

J. Blaas obtained from the pyritiferous trachytes of Madeni Zakh, Persia, yellow aggregates of minute six-sided plates, which he called **metavoltine**. F. Zambonini found the mineral in the Grotta di Zolfo, Miseno and Vesuvius; E. Aguilar, at the solfatara of Pozzuoli, Naples; and A. Lacroix, in a fumarole near Pyromeni, Island of Milo, and near Porto di Levante, Vulcano. Analyses reported by J. Blaas, F. Zambonini, and R. Scharizer correspond with the formula $5(\text{K}_2, \text{Na}_2, \text{Fe})\text{O} \cdot 3\text{Fe}_2\text{O}_3 \cdot 12\text{SO}_3 \cdot 18\text{H}_2\text{O}$, or, in the idealized case, $\text{K}_{10}\text{Fe}_6\text{S}_{12}\text{O}_{50} \cdot 18(\text{or } 19)\text{H}_2\text{O}$. R. Scharizer found that the dehydration curves—averaged for α -metavoltine in Fig. 673—correspond with losses of the order:

	34°	48°	75°	100°	134°	145°	154°	184°	243°
Loss . . .	4.15	5.77	6.35	7.44	10.13	11.71	13.04	14.05	14.71 per cent.

There are breaks at about 60° , 120° , and 130° , corresponding respectively with the

decahydrate, the pentahydrate, and the trihydrate. It is therefore supposed that four mols. of water are constitutional, and that the formula for metavoltine is: $\text{H}_2\text{K}_{10}[\text{Fe}(\text{OH})_6](\text{SO}_4)_{12} \cdot 14$ (or 15) H_2O . There are differences in the reported proportions of water of crystallization. R. Scharizer observed that when the crystals are left exposed to air, they crumble to powder. The original crystals correspond with $\text{H}_2\text{K}_{10}[\text{Fe}(\text{OH})_6](\text{SO}_4)_{12} \cdot 15\text{H}_2\text{O}$, and those which have crumbled to powder have only $12\text{H}_2\text{O}$, and are pseudomorphous with the original hexagonal crystals. B. Gössner and M. Arm gave $\text{K}_2\text{H}_7(\text{SO}_4)_6 \cdot 3\text{Fe}(\text{OH})_3 \cdot \text{H}_2\text{O}$ for the formula.

R. Scharizer observed that there are two forms of this salt, both of which have the formula: $\text{H}_2\text{K}_{10}[\text{Fe}(\text{OH})_6](\text{SO}_4)_{12} \cdot 15\text{H}_2\text{O}$. The ordinary form, called α -metavoltine, has hexagonal crystals, is optically negative, and has a sp. gr. of 2.403; the other form, called β -metavoltine, has triclinic crystals, is optically negative, and has a sp. gr. 2.339. Hexagonal α -metavoltine crystallizes easily from soln. of potassium and ferric sulphates containing an excess of one of these salts. The amount of potassium sulphate in excess is without influence, but with ferric sulphate certain limits must not be exceeded—*vide infra*, the hydrolysis of metavoltine. If the soln. of the two sulphates, acidified with sulphuric acid, be treated with alcohol, and the orange-red, gelatinous mass be left in contact with the mother-liquor for 24 hrs., crystals of α -metavoltine are formed. The exact conditions for the formation of β -metavoltine have not been determined, but a high concentration of substances which hinder the hydrolysis of the α -salt is necessary, and in some cases both the α - and β -salts crystallize from the same soln. The soln. of the α -salt is transformed into the β -salt when the liquid is mixed with substances which impart an acidity to the soln.—*e.g.*, sulphuric acid, potassium hydrosulphate, or rhomboclase—but not normal potassium sulphate. The transformation can be recognized as the green soln. becomes brown. B. Gössner and M. Arm prepared metavoltine by keeping a soln. of 300 grms. of water, 19.5 grms. potassium sulphate, and 27 grms. of ferric sulphate in a round flask on a sand-bath at 70° to 80° for some days. Metavoltine is obtained by evaporating the soln. at ordinary temp., but the product appears in the form of crystalline crusts.

B. Gössner and M. Arm found that nearly half the water of crystallization is lost at ordinary temp. in a short time. According to R. Scharizer, the dehydration curves of α - and β -metavoltine, Fig. 673, are similar, but the β -salt is rather more stable when heated in air. R. Scharizer also found that 100 parts of water at ordinary temp. dissolve 11.52 parts of α -metavoltine and 4.68 parts of potassium hydrosulphate, or else 7.04 parts of β -metavoltine and 4.62 parts of potassium hydrosulphate. Hence the β -salt appears to be the stable form, and the α -salt the labile form of metavoltine.

B. Gössner and M. Arm found that the hexagonal prisms have the axial ratio $a : c = 1 : 0.957$; and that the X-radiograms correspond with a unit cell containing 8 mols., and with the parameters $A = 19.43 \text{ \AA.}$, and $c = 18.60 \text{ \AA.}$ J. Blaas gave 2.53 for the sp. gr. of metavoltine; and B. Gössner and M. Arm gave 2.396; and found the mol. wt. to be 117.5. J. Blaas gave 2.5 for the hardness. The hexagonal, yellow crystals are pleochroic, ω is yellow to chestnut-brown, and ϵ , pale yellow or green. E. S. Larsen found the indices of refraction to be $\omega = 1.588$, and $\epsilon = 1.578$. Unlike copiapite, metavoltine is sparingly soluble in water. J. Blaas said that metavoltine dissolves slowly in hydrochloric acid, and slowly and imperfectly in cold water. The aq. soln. deposits a red powder when it is heated. R. Scharizer said that the aq. soln. of metavoltine is at first undecomposed, but hydrolysis sooner or later occurs according to the concentration. The metavoltine splits into potassium sulphate and an unstable residue, $\text{Fe}_6\text{S}_7\text{O}_{30}$, or $2\text{Fe}_2(\text{SO}_4)_3 \cdot \text{Fe}_2\text{O}_2(\text{SO}_4)$, then decomposes until the soluble part approximates to $\text{Fe}_2(\text{SO}_4)_3$, and utahite, $\text{Fe}_2\text{O}_2\text{SO}_4$, is precipitated. The ferric sulphate is hydrolyzed liberating sulphuric

FIG. 673.—Dehydration Curves of Metavoltine.

acid, which then forms with the potassium sulphate some hydrosulphate. As indicated above, the hydrolysis is hindered by substances which can give sulphuric acid, but not by potassium sulphate.

C. F. Rammelsberg described a yellow iron earth—*Gelbeisenerz*—from the brown coal deposit at Luschitz, Bohemia; W. Haidinger considered that it was like the *misy* of the early writers—*vide supra*; J. F. L. Hausmann called it yellow vitriol—*Vitriolgelb*; and C. U. Shepard named a sample from Monroe, New York, *moronolite*—from $\mu\acute{o}\rho\omicron\nu$, mulberry, in allusion to its resemblance to the mulberry calculus. A sample from Barranco Jaroso, Spain, was called by A. Breithaupt, **jarosite**. There are occurrences from the Vulture mine, Arizona; the Mammoth mine, Utah; Berezhoff, Ural; Cajamarca, Peru; Hauptmanngrün, Voigtland; Schwarzenberg, Erzgebirge; etc. Analyses were reported by S. L. Penfield, G. A. König, F. A. Genth, W. F. Hillebrand and co-workers, C. F. Rammelsberg, F. Kovar, T. Richter, J. H. Ferber, L. Azéma, W. T. Schaller, W. P. Headden, E. Manasse, R. C. Wells, T. Scheerer, P. P. Philipenko, and F. S. Simpson and M. A. Browne. The results correspond approximately with $K_2O \cdot 3Fe_2O_3 \cdot 4SO_3 \cdot 6H_2O$, and this can be arranged as **potassium ferric hydroxytetrasulphate**, $K_2O \cdot 3Fe_2O_3 \cdot 4SO_3 \cdot 6H_2O$, or $K_2[Fe(OH)_2]_6(SO_4)_4$, which recalls the formula for utahite: $[Fe(OH)_2]_2SO_4$. The formula can also be written: $K(FeO)_3(SO_4)_2 \cdot 3H_2O$. J. G. Fairchild synthesized the potassium jarosite by dissolving 0.17 grm. of potassium sulphate and 1.6 grms. of ferric sulphate in 20 c.c. of 0.75*N*- H_2SO_4 , and heated the soln. in a sealed pyrex glass tube for 24 hrs. at 110°; and 24 hrs. more at 165° to 180°. The crystals were washed in water.

The type formula is in agreement with the observation that when gently heated, jarosite suffers no change until, at about 105°, the substance decomposes chemically, producing a fine powder or dust which is carried along by the escaping vapours and deposited some distance along the sides of the tubes. In addition to water, sulphur dioxide and trioxide are copiously evolved. On ignition, one-fourth of the sulphate radicle is retained by the alkali metal—sodium or potassium. In some forms of jarosite, where lead takes the place of the alkali metal, all the sulphate is expelled. This is in agreement with the observation that although lead sulphate does not decompose under similar conditions, yet an intimate mixture of finely-powdered lead sulphate and ferric hydroxide gives off acid water when heated. The forms of jarosite from Soda Springs Valley, New Mexico; Buxton mine, South Dakota; Mine San Joy, Mexico; Mount Morgan, Queensland; and Capo Calamita Elba, analyzed by W. F. Hillebrand and co-workers, W. P. Headden, T. Cooksey, G. A. König, and E. Manasse, in which the potassium is wholly or in part replaced by sodium, are called **natrojarosite**, $Na_2[Fe(OH)_2]_6(SO_4)_4$, and samples from Cooks Peak, New Mexico; and American Fork, and Beaver Co., Utah. R. Jirkovsky studied sodium jarosite. A sample from Boss mine, Nevada, analyzed by W. F. Hillebrand and co-workers, R. C. Wells, and W. T. Schaller, had the potassium replaced by lead, **plumbojarosite**, $Pb[Fe(OH)_2]_6(SO_4)_4$. W. T. Schaller, and C. A. Schempp called an argentiferous variety from Utah, **argentojarosite**. J. G. Fairchild did not succeed in making *lithiojarosite*, *caesiojarosite*, *cuprojarosite*, or *aurojarosite*, but he prepared **rubidiojarosite**—uniaxial, and negative, with $\epsilon=1.720$ and $\omega=1.805$ —**argentojarosite**—uniaxial, and negative, with $\epsilon=1.785$ and $\omega=1.880$ —and **plumbojarosite**—uniaxial, and negative, with $\epsilon=1.783$ and $\omega=1.870$. E. V. Shannon found some ochreous nodules corresponding with **ammoniojarosite**, $(NH_4)_2O \cdot Fe_2O_3 \cdot 4SO_3 \cdot 6H_2O$, probably obtained from Utah. R. Jirkovsky studied the salt. The formula can be represented graphically by one or other of the following:

W. F. Hillebrand and S. L. Penfield consider that the jarosites are solfataric products having been formed under the combined action of heat and press. Their sparing solubility explains how they occur as fine crystalline powders like many precipitates. A. Mitscherlich obtained jarosite by heating a mixture of ferric and potassium sulphates in a sealed tube at 260° .

Jarosite is coloured ochre-yellow, yellowish-brown, or clove-brown. It occurs in minute, indistinct crystals in druses, and less frequently in rhombohedral crystals somewhat resembling cubes with tetrahedral planes. The mineral also occurs in fibrous, or compact masses, and in nodules or incrustations with a tuberoso or coral-loidal surface. The rhombohedral crystals were found by G. A. König to have the axial ratio $a : c = 1 : 1.2492$; and W. F. Hillebrand and S. L. Penfield gave $1 : 1.245$ for jarosite; $1 : 1.216$ for plumbojarosite; and $1 : 1.104$ for natrojarosite. G. Cesaro's value, $1 : 1.1689$, probably referred to a mixed jarosite. The crystals were also studied by A. Breithaupt, and N. von Kokscharoff. W. F. Hillebrand and F. E. Wright found a specimen of plumbojarosite which was pleochroic, c being dark brownish-red, and a pale golden-yellow. The (0001)-cleavage is distinct. According to J. G. Fairchild, the crystals are uniaxial and optically negative, with the indices of refraction $\epsilon = 1.71$ and $\omega = 1.80$. E. S. Larsen gave $\omega = 1.82$.

According to W. F. Hillebrand and S. L. Penfield, the jarosite family may be taken to include the alunites so as to furnish the isomorphous series :

Alunite	$K_2[Al(OH)_2]_6(SO_4)_4$
Natroalunite	$Na_2[Al(OH)_2]_6(SO_4)_4$
Jarosite	$K_2[Fe(OH)_2]_6(SO_4)_4$
Ammoniojarosite	$(NH_4)_2[Fe(OH)_2]_6(SO_4)_4$
Natrojarosite	$Na_2[Fe(OH)_2]_6(SO_4)_4$
Argentojarosite	$Ag_2[Fe(OH)_2]_6(SO_4)_4$
Plumbojarosite	$Pb[Fe(OH)_2]_6(SO_4)_4$
Carphosiderite	$H_2[Fe(OH)_2]_6(SO_4)_4$

Carphosiderite was added to the series by W. T. Schaller. W. F. Hillebrand and S. L. Penfield continued : Assuming that these represent the mol. formulæ, there are in each molecule fifty atoms, to one Pb-atom or one group K_2 or Na_2 . Hence, these fifty atoms, by virtue of their mass effect, dominate the situation, and an isomorphism between such unlike elements as potassium, sodium, and lead is not so surprising as might at first appear. Although the K_2 , Na_2 , and Pb units play so small a part in these molecules, the substitution of Na_2 for K_2 is attended by a marked variation in the angles of the crystals, greater, in fact, than is generally observed in isomorphous replacements. The likeness between alunite and jarosite would be anticipated from the closeness of the axial ratios of corundum, Al_2O_3 , and hæmatite, Fe_2O_3 , since the ratios $a : c$, for the two minerals, are respectively $1 : 3630$, and $1 : 3656$. The lengths of the c -axis in these minerals are :

Alunite	Jarosite	Natrojarosite	Plumbojarosite
1.252	1.245	1.104	1.216

so that the substitution of sodium for potassium in jarosite produces a greater variation than the substitution of Pb for K_2 . The optical character of the jarosites is positive ; that of alunite is negative. E. S. Larsen gave for the indices of refraction of natrojarosite, $\omega = 1.832$, and $\epsilon = 1.750$, or $\omega - \epsilon = 0.082$, and for plumbojarosite, $\omega = 1.875$, and $\epsilon = 1.784$, or $\omega - \epsilon = 0.091$. W. F. Hillebrand and F. E. Wright gave for plumbojarosite, $\omega = > 1.825$, and $\epsilon = 1.785$, and said that the crystals in convergent polarized light are uniaxial, optically negative and with a strong birefringence. The sp. gr. of jarosite is 3.15 to 3.26 ; and the hardness 2.5 to 3.5 . D. Mawson observed that the mineral is readily decomposed by ammonia—liquid, soln., or gas.

R. Scharizer prepared **potassium ferric trisulphate**, $K_6Fe_2(SO_4)_6 \cdot nH_2O$, or $Fe(KSO_4)_3 \cdot nH_2O$, analogous to ferrinatrinite (*q.v.*), and he accordingly named it **ferrikalite**.

H. Erdmann, C. Soret, M. le Blanc and P. Rohland¹ prepared **rubidium ferric disulphate**, $RbFe(SO_4)_2 \cdot 12H_2O$, or **rubidium ferric alum**, $Rb_2SO_4 \cdot Fe_2(SO_4)_3 \cdot 24H_2O$,

from a soln. of the constituent salts, and J. L. Howe and E. A. O'Neal, by the electrolytic method employed for the ammonium salt. The octahedral crystals are colourless or a delicate violet; they are isomorphous with the members of the alum family. C. Soret gave 1.916 for the sp. gr.; and M. le Blanc and P. Rohland gave 1.952 for the solid, and 1.0381 and 1.0575 respectively for soln. with 7.11 and 10.55 per cent. of the salt—*vide supra*. J. Locke found that the salt melts in its water of crystallization at 53°. H. Erdmann said 33°. C. Soret found for the index of refraction, μ :

	A-	B-	C-	D-	E-	b-	F-	G-light
μ	1.47700	1.47770	1.47894	1.48234	1.48654	1.48712	1.49003	1.49700

M. le Blanc and P. Rohland gave $\mu=1.4823$ for the solid with Na-light; and 1.3395 and 1.3427 respectively for soln. with 7.11 and 10.55 per cent. of salt. The corresponding sp. and mol. refractions with the μ -formula are 0.2501 and 36.36 and with the μ^2 -formula, 0.1489 and 20.46 for the soln. with 7.11 per cent. of salt; and for soln. with 10.55 per cent. of salt, and the μ -formula respectively 0.2488 and 34.19, and with the μ^2 -formula, 0.1485 and 20.40. The crystals acquire a green tinge on exposure to air. J. Locke found the solubilities in water at 25° and 30° to be respectively 97.4 and 202.4 grms. $\text{Rb.Fe(SO}_4)_2$ per litre; at 35° and 40°, the soln. decomposes precipitating a basic salt.

C. Soret prepared **cæsium ferric disulphate**, $\text{CsFe(SO}_4)_2 \cdot 12\text{H}_2\text{O}$, or *cæsium ferric alum*, $\text{Cs}_2\text{SO}_4 \cdot \text{Fe}_2(\text{SO}_4)_3 \cdot 24\text{H}_2\text{O}$, from a soln. of the component salts; and J. L. Howe and E. A. O'Neal, by the electrolytic process used for the ammonium salt. The octahedral crystals are colourless or a delicate violet, and the crystals acquire a green tinge on exposure to air. They are isomorphous with the members of the alum family. C. Soret gave 2.061 for the sp. gr.—*vide supra*. J. Locke found that the salt melts in its water of crystallization at 71°. C. Soret gave for the index of refraction, μ :

	A-	B-	C-	D-	E-	b-	F-	G-light
μ	1.47825	1.47921	1.48042	1.48378	1.48797	1.48867	1.49136	1.49838

J. Locke found the solubilities of the salt in water at 25°, 30°, 35°, and 40° to be respectively 17.1, 25.2, 37.5, and 60.4 grms. of $\text{CsFe(SO}_4)_2$ per litre.

A. Raimondi, and I. Domeyko described a lemon-yellow or orange-yellow mineral occurring in the San Simon mine, Huantajaya, Chili, and it was called **sideronatrite**. Analyses reported by A. Raimondi, A. Frenzel, and F. A. Genth correspond with $2\text{Na}_2\text{O} \cdot \text{Fe}_2\text{O}_3 \cdot 4\text{SO}_3 \cdot 7\text{H}_2\text{O}$. F. A. Genth observed that about 4 mols. of water are lost at 110°, and A. Frenzel, that all is lost at 300°. R. Scharizer found that sideronatrite with 14.63 per cent. of water loses 9.43 per cent. of water in a desiccator; while at 100° it loses 10.30 per cent.; at 125°, 4.13 per cent.; at 165°, 0.15 per cent., and at 205°, 0.05 per cent. This means that 6 mols. of water are lost at 125°, and the remaining mol. at higher temp. Allowing for the mol. of constitutional water, the formula can be written: $[\text{NaSO}_4]_4[\text{Fe(OH)}]_2 \cdot 6\text{H}_2\text{O}$, or **sodium ferric hydrodisulphate**, $(\text{NaSO}_4)_2\text{Fe(OH)} \cdot 3\text{H}_2\text{O}$, analogous with potassium ferric dihydrosulphate. A. Skrabal synthesized the mineral by heating a soln. of 50 grms. of ferric sulphate and 10 c.c. of dil. sulphuric acid (1 : 6) with 300 grms. of hydrated sodium sulphate on a water-bath. R. Scharizer crystallized soln. of ferric sulphate, or acid sulphate and sodium sulphate, and obtained sideronatrite so long as the proportion of sulphuric acid in the soln. is not too great, and the proportion of $\text{Na}_2\text{O} : \text{Fe}_2\text{O}_3$ is less than about 2, otherwise ferrinatrite is formed.

Sideronatrite occurs in orange-yellow or straw-yellow, crystalline masses of fine, fibrous structure which separate into thin splinters. S. L. Penfield found that the crystals are rhombic; A. Raimondi said monoclinic; and A. Frenzel, triclinic. The cleavage is probably pinacoidal. The optical character is positive. Pleochroism is not very marked—F. A. Genth said that *a* and *b* are colourless, and *c* is straw-yellow, and E. S. Larsen, that *a* is colourless, *b* is pale amber-yellow, and *c* is amber-yellow. The optic axial angle $\alpha V=58^\circ 5'$; and the indices of

refraction $\alpha=1.508$, $\beta=1.525$, and $\gamma=1.586$. The sp. gr. given by F. A. Genth is 2.153, and by S. L. Penfield, 2.355; the hardness is 2.0 to 2.5. The mineral is virtually insoluble in cold water, but is decomposed by boiling water with the separation of hydrated ferric oxide. It is soluble in acids.

A. Frenzel described a lemon-yellow or orange-yellow mineral which he called *urusite*, obtained from the Urus plateau, on the naphtha island Cheleken, in the Caspian Sea. It occurs in pulverulent earthy forms, and also in lumps consisting of minute, rhombic crystals. The composition is very close to that of sideronatrite, being $2\text{Na}_2\text{O} \cdot \text{Fe}_2\text{O}_3 \cdot 4\text{SO}_3 \cdot 8\text{H}_2\text{O}$, so that J. D. Dana considered both to be the same mineral species. The sp. gr. is 2.22. P. T. Cleve described an impure sideronatrite obtained from St. Bartholomew, West Indies, and he called it *bartholomite*. Its composition, allowing for impurities, is $2\text{N}_2\text{O} \cdot \text{Fe}_2\text{O}_3 \cdot 4\text{SO}_3 \cdot 3\text{H}_2\text{O}$.

J. B. Macintosh described a mineral from Sierra Gorda, Chili, which he called *ferrinatrite*, but since the contained iron is ferric, not ferrous, R. Scharizer altered it to **ferrinatrite**. A. Frenzel called the mineral *gordaitite*. Analyses reported by J. B. Macintosh, F. A. Genth, and A. Frenzel agree with the formula: $3\text{Na}_2\text{O} \cdot \text{Fe}_2\text{O}_3 \cdot 6\text{SO}_3 \cdot 6\text{H}_2\text{O}$. F. A. Genth said 3 mols. of water are lost at 100° , and J. B. Macintosh 5.5 mols.; and R. Scharizer observed that nearly all the water is lost at 100° , so that none is considered to be constitutional water, and he wrote the formula: $\text{Fe}_2(\text{NaSO}_4)_6 \cdot 6\text{H}_2\text{O}$, or **sodium ferric trisulphate**, $\text{Fe}(\text{NaSO}_4)_3 \cdot 3\text{H}_2\text{O}$. R. F. Weinland and F. Engraber wrote the formula: $\text{Na}_3[\text{Fe}(\text{SO}_4)_3] \cdot 3\text{H}_2\text{O}$. A. Skrabal prepared this salt by melting sodium sulphate in its water of crystallization, and adding ferric sulphate and conc. sulphuric acid. R. F. Weinland and F. Engraber prepared the salt by mixing a soln. of 0.01 mol of ferric sulphate in 50 c.c. of water, with 0.03 to 0.05 mol of sodium sulphate in 50 c.c. of water, and 0.08 mol of sulphuric acid; heating the mixture on a water-bath until half the water had evaporated; and allowing the mixture to cool slowly for 24 hrs. R. Scharizer obtained it by allowing a mixture of ferric and sodium acid sulphates to stand for some time in moist air; and also by employing the method used for the preparation of sideronatrite but using soln. strongly acidified with sulphuric acid. R. Scharizer observed that if ferrinatrite be allowed to stand in moist air for a long time it passes into sideronatrite; and conversely, if sideronatrite be allowed to stand in a conc. sulphuric acid soln., it passes into ferrinatrite.

Ferrinatrite is white, may be pale green or pale grey. It rarely occurs in distinct acicular crystals, more usually in spherical forms with a lamellar and stellate structure. According to A. Arzruni, the rhombohedral crystals have the axial ratio $a:c=1:0.55278$. The $(10\bar{1}0)$ -cleavage is perfect, but the $(11\bar{2}0)$ -cleavage is not so distinct. The optical character of the uniaxial crystals is positive. S. L. Penfield gave for the indices of refraction for yellow-light, $\omega=1.558$ and $\epsilon=1.613$; and F. Zambonini, $\omega=1.5559$ and $\epsilon=1.627$. F. A. Genth gave 2.547 to 2.578 for the sp. gr., and 2 for the hardness. Ferrinatrite is soluble in water, and insoluble in alcohol. For **sodium ferric hydroxytetrasulphate**, *vide supra*, natrojarosite. H. Ungemach described **amarillite**, $\text{NaFe}(\text{SO}_4)_2 \cdot 6\text{H}_2\text{O}$, in pale yellow, monoclinic crystals from Tierra Amarilla, Chili. The axial ratios are $a:b:c=0.7757:1:1.1482$, and $\beta=84^\circ 33'$.

R. Jirovsky and F. Ulrich applied the term **slavikite**—after F. Slavik—to small, tabular, rhombohedral crystals with the axial ratio $a:c=1:1.03$, found at Valachov, Czechoslovakia. The analysis corresponds with $(\text{Na},\text{K})_2\text{SO}_4 \cdot \text{Fe}_{10}(\text{HO})_4(\text{SO}_4)_{12} \cdot 63\text{H}_2\text{O}$. The crystals are pleochroic being greenish-yellow parallel to c , and colourless perpendicular to c . The optical character of the uniaxial crystals is negative; and the indices of refraction for sodium light are $\omega=1.530$, and $\epsilon=1.506$. The sp. gr. is 1.905.

G. Tunell and E. Posnjak studied a portion of the quaternary system: $\text{CuO}-\text{Fe}_2\text{O}_3-\text{SO}_3-\text{H}_2\text{O}$ in the region involving 93.5 per cent. or more H_2O ; 6.5 per cent. or less of Fe_2O_3 ; 6.5 per cent. or less of CuO ; and 6.5 per cent. or less of SO_3 at 50° . The results are summarized in Figs. 674 and 675 on the surfaces of an equilateral tetrahedron. There are five crystalline phases: $\text{Fe}_2\text{O}_3 \cdot \text{H}_2\text{O}$ (geo-

thite); $3\text{Fe}_2\text{O}_3 \cdot 4\text{SO}_3 \cdot 9\text{H}_2\text{O}$; CuO (tenorite); $4\text{CuO} \cdot \text{SO}_3 \cdot 3\text{H}_2\text{O}$ (brochantite); and $3\text{CuO} \cdot \text{SO}_3 \cdot 2\text{H}_2\text{O}$ (antlerite), in this portion of the system, but no double salt was stable in this region. The $\text{Fe}_2\text{O}_3 \cdot \text{H}_2\text{O}$ saturation surface in the quaternary system extends from the saturation curve of $\text{Fe}_2\text{O}_3 \cdot \text{H}_2\text{O}$ in the system, $\text{Fe}_2\text{O}_3 \cdot \text{SO}_3 \cdot \text{H}_2\text{O}$, almost to the saturation curves of $4\text{CuO} \cdot \text{SO}_3 \cdot 3\text{H}_2\text{O}$ and $3\text{CuO} \cdot \text{SO}_3 \cdot 2\text{H}_2\text{O}$ in the system, $\text{CuO} \cdot \text{SO}_3 \cdot \text{H}_2\text{O}$, the three-phase curves, $\text{Fe}_2\text{O}_3 \cdot \text{H}_2\text{O}$, $4\text{CuO} \cdot \text{SO}_3 \cdot 3\text{H}_2\text{O}$, solution, and $\text{Fe}_2\text{O}_3 \cdot \text{H}_2\text{O}$, $3\text{CuO} \cdot \text{SO}_3 \cdot 2\text{H}_2\text{O}$, solution, lying extremely close to the saturation curves of $4\text{CuO} \cdot \text{SO}_3 \cdot 3\text{H}_2\text{O}$ and $3\text{CuO} \cdot \text{SO}_3 \cdot 2\text{H}_2\text{O}$ in the system, $\text{CuO} \cdot \text{SO}_3 \cdot \text{H}_2\text{O}$. Again, the 3-phase curve: $\text{Fe}_2\text{O}_3 \cdot \text{H}_2\text{O}$, $3\text{Fe}_2\text{O}_3 \cdot 4\text{SO}_3 \cdot 9\text{H}_2\text{O}$, solution, extending from the triple point: $\text{Fe}_2\text{O}_3 \cdot \text{H}_2\text{O}$, $3\text{Fe}_2\text{O}_3 \cdot 4\text{SO}_3 \cdot 9\text{H}_2\text{O}$, solution, of the system, $\text{Fe}_2\text{O}_3 \cdot \text{SO}_3 \cdot \text{H}_2\text{O}$, at successively higher CuO percentages intersects planes parallel to the $\text{Fe}_2\text{O}_3 \cdot \text{CuO} \cdot \text{SO}_3$ face of the co-ordinate tetrahedron in which the percentage of H_2O is successively lower (the planes referred to are those in any one of which the percentage of H_2O is a constant); Fig. 674 is a perspective view of a model of the isothermal-isobaric saturation surface in the portion of the

FIGS. 674 and 675.—Portion of the Quaternary System: $\text{Fe}_2\text{O}_3\text{--CuO--SO}_3\text{--H}_2\text{O}$, at 50° .

system, $\text{Fe}_2\text{O}_3\text{--CuO--SO}_3\text{--H}_2\text{O}$, in which the total composition is 93.5 per cent. or more H_2O , 6.5 per cent. or less Fe_2O_3 , 6.5 per cent. or less CuO , and 6.5 per cent. or less SO_3 ; and Fig. 675 is a perspective view of a model of the isothermal-isobaric saturation surface in the portion of the system, $\text{Fe}_2\text{O}_3\text{--CuO--SO}_3\text{--H}_2\text{O}$, in which the total composition is 93.5 per cent. or more H_2O , 6.5 per cent. or less Fe_2O_3 , 6.5 per cent. or less CuO , and 6.5 per cent. or less SO_3 .

W. Bastick prepared **copper ferric tetrasulphate**, $\text{Cu}[\text{Fe}(\text{SO}_4)_2]_2 \cdot 24\text{H}_2\text{O}$, or **copper ferric alum**, $\text{CuSO}_4 \cdot \text{Fe}_2(\text{SO}_4)_3 \cdot 24\text{H}_2\text{O}$, from an acid soln. of eq. proportions of the component salts. In addition to the *tetracosihydrate*, C. Lausen observed a *heptahydrate* of copper ferric tetrasulphate, $\text{CuO} \cdot \text{Fe}_2\text{O}_3 \cdot 4\text{SO}_3 \cdot 7\text{H}_2\text{O}$, occurring in sky-blue, rhombic crystals, and the mineral was named **ransomite**—after F. L. Ransome. It was formed by the burning of pyritic ore in a mine at Jerome, Arizona. The rhombic crystals have the axial ratios $a : b : c = 1.7407 : 1 : 0.5168$. The cleavage—either pinacoidal or prismatic—is perfect. The sp. gr. is 2.632; the hardness is 2.5; the optical character is positive; and the indices of refraction are $\alpha = 1.631$, $\beta = 1.643$, and $\gamma = 1.695$. The crystals of **guildite** found in the same locality are dark chestnut-brown and monoclinic with the axial ratios $a : b : c = 1.037 : 1 : 1.407$, and $\beta = 74^\circ 43'$. The composition approximates $3(\text{Cu}, \text{Fe})\text{O} \cdot 2(\text{Fe}, \text{Al})_2\text{O}_3 \cdot 7\text{SO}_3 \cdot 17\text{H}_2\text{O}$; the sp. gr. is 2.725; the hardness is 2.5; the optical character is positive; and the indices of refraction are $\alpha = 1.623$, $\beta = 1.630$, and $\gamma = 1.684$. For **silver ferric hydrotetrasulphate**, $\text{Ag}_2\text{O} \cdot 3\text{Fe}_2\text{O}_3 \cdot 4\text{SO}_3 \cdot \text{H}_2\text{O}$, *vide supra*, argentojarosite.

According to Z. Karaoglanoff, barium sulphate can adsorb a little ferric sulphate from aq. soln., and when barium chloride is added to soln. of sulphuric acid or soluble sulphates containing ferric salts, the precipitated barium sulphate is contaminated with iron either adsorbed or in solid soln. G. McP. Smith, however, considers that an insoluble compound—**barium ferric disulphate**, $\text{Ba}[\text{Fe}(\text{SO}_4)_2]_2 \cdot n\text{H}_2\text{O}$ —is formed.

W. Bastick prepared **magnesium ferric tetrasulphate**, $\text{Mg}[\text{Fe}(\text{SO}_4)_2]_2 \cdot 24\text{H}_2\text{O}$, or *magnesium ferric alum*, $\text{MgSO}_4 \cdot \text{Fe}_2(\text{SO}_4)_3 \cdot 24\text{H}_2\text{O}$, from a soln. of eq. proportions of the component salts acidified with sulphuric acid.

J. J. Berzelius described a *rother Eisenvitriol*, from Falun, Sweden, which was called **botryogen**—from *βότρυς*, a bunch of grapes, and *-γενής*, producing—by W. Haidinger, and *botryite*, or rather *botryte*, by E. F. Glocker; F. S. Beudant called it *neophase*; and A. S. Eakle, *palacheite*—after C. Palache. The mineral also occurs in Madeni Zakh, Persia, at Knoxville, California, and in Peru. Analyses reported by J. G. Gahn and J. J. Berzelius, J. Blaas, R. Mauzelius, P. T. Cleve, J. Hockauf, and A. S. Eakle correspond with $2\text{MgO} \cdot \text{Fe}_2\text{O}_3 \cdot 4\text{SO}_3 \cdot 15\text{H}_2\text{O}$. H. Sjögren gave $\text{Mg}(\text{FeOH})(\text{SO}_4)_2 \cdot 7\text{H}_2\text{O}$. A. S. Eakle found that at 160° , four-fifths of the water is given off; R. Scharizer regarded this as water of crystallization, and he wrote the formula: $(\text{MgOH})_2(\text{FeOH})_2(\text{SO}_4)_2(\text{HSO}_4)_2 \cdot 12\text{H}_2\text{O}$, or $\text{H}_2(\text{MgOH})_2(\text{FeOH})_2(\text{SO}_4)_4 \cdot 12\text{H}_2\text{O}$. The former is analogous to A. Recoura's ferrisulphuric acid, and the constitutional formula represents the salt as **magnesium ferric trihydrodisulphate**:

Botryogen is deep hyacinth-red, or when massive, sometimes ochre-yellow. It usually occurs in reniform or botryoidal shapes or globules with a crystalline surface. It may occur in short, prismatic crystals with the (110)- and (120)-faces vertically striated. The crystals are monoclinic, and $\beta=62^\circ 26\frac{1}{2}'$; A. S. Eakle gave $0.6554:1:0.3996$, and $\beta=117^\circ 9'$, whilst R. Scharizer, with a different orientation, gave $1.2245:1:0.8265$, and $\beta=99^\circ 35'$. The (110)-cleavage is distinct; and the (120)-cleavage in traces. The pleochroic-crystals parallel to *c* are orange, and vertical to *c*, orange-grey; E. S. Larsen gave *a* pale yellow, *b* pale red, and *c* orange. The indices of refraction are $\alpha=1.544$, $\beta=1.548$, and $\gamma=1.572$ for sodium light. The optical axial angle $2V=40^\circ 54'$. R. Mauzelius gave 2.13 for the sp. gr., and A. S. Eakle, 2.13. The hardness is 2.0 to 2.5. The mineral is stable in a dry atm., but in a moist atm. it becomes covered with a dirty yellowish powder. It is partly soluble in water, leaving an ochreous residue.

A. Frenzel described a reddish-brown mineral from the Salvador mine, Quetena, Chili, which he called **quetenite**. The analysis corresponds with $\text{MgO} \cdot \text{Fe}_2\text{O}_3 \cdot 3\text{SO}_3 \cdot 13\text{H}_2\text{O}$, and it can be represented as **magnesium ferric tetrahydrotrisulphate**:

Quetenite occurs in indistinct crystalline masses or in monoclinic or triclinic crystals, with the prismatic cleavage very distinct. The pleochroism has *a* and *b* colourless, and *c* orange-yellow. E. S. Larsen gave for the optic axial angle, $2V=32^\circ$, and for the indices of refraction $\alpha=1.530$, $\beta=1.535$, and $\gamma=1.595$. A. Frenzel gave 2.08 to 2.14 for the sp. gr., and 3 for the hardness. The mineral is decomposed by water with the separation of hydrated ferric oxide.

L. Darapsky described a mineral from Rio Loa, Atacama, which he called **cubeite**. The analysis corresponds with $3\text{MgO} \cdot 2\text{Fe}_2\text{O}_3 \cdot 7\text{SO}_3 \cdot 3\text{H}_2\text{O}$, or perhaps better with $3(\text{Mg},\text{Ca})\text{O} \cdot 2(\text{Fe},\text{Al})_2\text{O}_3 \cdot 7\text{SO}_3 \cdot 3\text{H}_2\text{O}$. It occurs in red, elongated pyramids either monoclinic or rhombic.

W. Bastick prepared **zinc ferric tetrasulphate**, $\text{Zn}[\text{Fe}(\text{SO}_4)_2]_2 \cdot 24\text{H}_2\text{O}$, or *zinc ferric alum*, $\text{ZnSO}_4 \cdot \text{Fe}_2(\text{SO}_4)_3 \cdot 24\text{H}_2\text{O}$, by crystallization from a soln. of eq. proportions of the component salts acidified with sulphuric acid. In addition to this *tetracosihydrate*, R. Scharizer prepared the *tetradecahydrate*, $\text{ZnSO}_4 \cdot \text{Fe}_2(\text{SO}_4)_3 \cdot 14\text{H}_2\text{O}$, by allowing a mixture of zinc sulphate and rhomboclase to stand in contact with moist air for several months. R. Scharizer called it **zinc-römerite**—*vide infra*.

A. Étard prepared **aluminium ferric hydrosulphate**, $\text{Al}_2(\text{SO}_4)_3 \cdot \text{Fe}_2(\text{SO}_4)_3 \cdot \text{H}_2\text{SO}_4$,

in microscopic hexagonal plates, by heating to 200° a conc. soln. of 2 mols of ferrous sulphate and a mol of aluminium chloride which had been mixed with nitric acid, and a large excess of sulphuric acid. The sandy deposit was separated by decantation, washed with glacial acetic acid, and dried at 120°. When heated to dull redness, sulphuric acid is evolved, and $\text{Al}_2(\text{SO}_4)_3 \cdot \text{Fe}_2(\text{SO}_4)_3$ remains as a white, crystalline, insoluble powder. F. Wirth and B. Bakke observed that the solubility of either ferric or aluminium sulphate in water at 25° is lowered by the addition of the other salt. At 25°, 100 grms. of the soln. contain :

$\text{Al}_2(\text{SO}_4)_3$	—	5.200	5.200	6.626	8.810	10.03	(10.23)	(10.70)
$\text{Fe}_2(\text{SO}_4)_3$	44.97	42.44	38.83	35.82	34.02	32.42	(31.90)	(31.91)

The brackets indicate that both salts are present in the solid phase. The solubility curves—mols of salt per 1000 grms. liquid, Fig. 676—meet when the

FIG. 676.—Mutual Solubility of Aluminium and Ferric Sulphates.

FIG. 677.—Composition of Solution and Solid for Mixtures of Potassium Aluminium and Potassium Ferric Alums.

FIG. 678.—Vapour Pressures of Solid Solutions of Potassium Aluminium and Potassium Ferric Alums.

ratio Fe:Al is 1:0.3831. There is no evidence of the formation of a compound or solid soln. H. Ungemach described **lapparentite**, $(\text{Al},\text{Fe})_2\text{O}_3 \cdot 2\text{SO}_3 \cdot 10\text{H}_2\text{O}$, from Tierra Amarilla, Chili, with monoclinic crystals having the axial ratios $a:b:c=0.2919:1:0.24155$, and $\alpha=85^\circ 10'$. R. Holleman found that *potassium aluminium ferric alums* form mixed crystals in all proportions and are isomorphous. Fig. 677 shows the relation between the composition of the soln. and that of the crystals. The vap. press. of the pure salts are respectively 2 mm. and 10.9 mm. There are minima in the vap. press. curve at 1.4 and 7.9 mm., and a maximum at 8.1 mm. when Fe:Al=2:1—Fig. 678. T. Klobb prepared solid soln. of *ammonium aluminium ferric alums*, $(\text{NH}_4)_2\text{SO}_4 \cdot (\text{Fe},\text{Al})_2(\text{SO}_4)_3 \cdot 24\text{H}_2\text{O}$.

J. E. Willm prepared pale yellow octahedra of **thallous ferric disulphate**, $\text{TlFe}(\text{SO}_4)_2 \cdot 12\text{H}_2\text{O}$, or **thallous ferric alum**, $\text{Tl}_2\text{SO}_4 \cdot \text{Fe}_2(\text{SO}_4)_3 \cdot 24\text{H}_2\text{O}$, from a soln. of the component salts. C. Soret gave 2.385 for the sp. gr., and O. Pettersson, 2.351. F. Ephraim and P. Wagner discussed the mol. vol.—*vide supra*. J. Locke found that the salt melted at 37° in its water of crystallization. C. Soret found the indices of refraction, μ , to be :

	A-	B-	C-	D-	E-	b-	F-	G-light
μ .	1.51674	1.51790	1.51943	1.52365	1.52850	1.52946	1.53284	1.54112

The salt is not efflorescent, and it is readily soluble in water. J. Locke found that 361.5 grms. of the anhydrous salt or 646 grms. of the hydrate are soluble in a litre of water at 25°; or 0.799 mol of the salt in a litre of water at 25°.

A. Knopf described a hydrated **lead ferric oxytrisulphate**, $\text{PbO} \cdot 3\text{Fe}_2\text{O}_3 \cdot 3\text{SO}_3 \cdot 6\text{H}_2\text{O}$, differing from *plumbojarosite*, $\text{PbO} \cdot 3\text{Fe}_2\text{O}_3 \cdot 4\text{SO}_3 \cdot 6\text{H}_2\text{O}$; it was obtained from Clark Co., Nevada, and was called **vegassite**—after Las Vegas, the chief town of the county. It occurs in straw-yellow, ochreous masses consisting of minute fibres and six-sided plates which are optically uniaxial. For *plumbojarosite*, **lead ferric hydroxytetrasulphate**, *vide supra*. B. S. Butler and W. T. Schaller described canary-yellow, earthy, friable masses consisting of microscopic, six-sided

plates, from Beaver Co., Utah; and the mineral was called **beaverite**. It is a **copper lead ferric trioxysulphate**, $\text{CuO} \cdot \text{PbO} \cdot \text{Fe}_2\text{O}_3 \cdot 2\text{SO}_3 \cdot 4\text{H}_2\text{O}$.

A. Étard prepared **chromic ferric hydrosulphate**, $\text{Cr}_2(\text{SO}_4)_3 \cdot \text{Fe}_2(\text{SO}_4)_3 \cdot \text{H}_2\text{SO}_4$, by the method used for the corresponding aluminium compound. When heated to dull redness it yields the anhydrous salt $\text{Cr}_2(\text{SO}_4)_3 \cdot \text{Fe}_2(\text{SO}_4)_3$. T. Klobb prepared solid soln. of *ammonium chromium ferric alums*, $(\text{NH}_4)_2\text{SO}_4 \cdot (\text{Cr}, \text{Fe})_2(\text{SO}_4)_3 \cdot 24\text{H}_2\text{O}$. N. Bjerrum and G. H. Hansen prepared **chromic ferric bromosulphate**, $[\text{CrBr}_2(\text{H}_2\text{O})_4][\text{Fe}(\text{H}_2\text{O})_6]\text{SO}_4 \cdot 2\text{H}_2\text{O}$, but not the corresponding chlorosulphate. A. Étard prepared **manganic ferric hydrosulphate**, $\text{Mn}_2(\text{SO}_4)_3 \cdot \text{Fe}_2(\text{SO}_4)_3 \cdot \text{H}_2\text{SO}_4$, by heating to 250° , the proper proportions of the two sulphates with a mixture of equal vols. of nitric and sulphuric acids added in small quantities at a time. This salt can be converted into $\text{Mn}_2(\text{SO}_4)_3 \cdot \text{Fe}_2(\text{SO}_4)_3$ by heat. He also prepared **manganous ferric hydrosulphate**, $2\text{MnSO}_4 \cdot \text{Fe}_2(\text{SO}_4)_3 \cdot 3\text{H}_2\text{SO}_4$, as well as $2\text{MnSO}_4 \cdot \text{Fe}_2(\text{SO}_4)_3 \cdot \text{H}_2\text{SO}_4$.

J. Sebor described an alum, **ferrous ferric tetrasulphate**, $\text{Fe}'[\text{Fe}(\text{SO}_4)]_2 \cdot 24\text{H}_2\text{O}$, or *ferrosic tetrasulphate*, or *ferrous ferric alum*, $\text{FeSO}_4 \cdot \text{Fe}_2(\text{SO}_4)_3 \cdot 24\text{H}_2\text{O}$, occurring in white or yellowish-white, radially fibrous masses in the Schwaz lignites near Bilin, Bohemia; and he called the mineral **bilinite**. The sp. gr. of bilinite is 1.875; the hardness, 2; and the index of refraction between 1.495 and 1.501. The double refraction of the acicular crystals is low. In addition to the *tetracosihydrate* just indicated, the *tetradecahydrate* occurs as a mineral which J. Grailich called **römerite**—after A. Römer—and G. Linck called it *bückingite*. It has been found at Goslar, Harz; Rio Tinto, Spain; Madeni Zagh, Persia; and Tierra Amarilla, Chili. Analyses reported by G. Tschermak, R. Scharizer, G. Linck, L. Darapsky, R. E. Landon, H. F. Collins, and J. Blaas, correspond with ferrous ferric tetrasulphate, $\text{FeO} \cdot \text{Fe}_2\text{O}_3 \cdot 4\text{SO}_3 \cdot 14\text{H}_2\text{O}$, or better, $(\text{Fe}, \text{Zn}, \text{Mg})\text{O} \cdot \text{Fe}_2\text{O}_3 \cdot 4\text{SO}_3 \cdot 14\text{H}_2\text{O}$, or $\text{FeSO}_4 \cdot \text{Fe}_2(\text{SO}_4)_3 \cdot 14\text{H}_2\text{O}$. R. Scharizer found that no water is lost by römerite in a desiccator over conc. sulphuric acid; water begins to come off at about 70° , and the reddish-brown powder then becomes bluish-black. The mineral loses 12 mols. of water below 130° , while very little is lost between 130° and 250° , beyond which temp. the remaining water is expelled. Two mols. of water are accordingly regarded as constitutional, and the formula may be written:

C. A. Anderson observed that the mineral in the United Verde mine, Jerome, Arizona, was probably formed by the action of vapours from burning sulphide ores. R. Scharizer synthesized the mineral by allowing a mixture of powdered ferrous sulphate, and rhomboclase to remain in contact with moist air for several months; it was also prepared from a soln. of the constituent salts in which the concentration exceeds a certain minimum, and in the presence of an excess of sulphuric acid. A soln. with the equivalent of 33.75 per cent. römerite; 8.98 per cent. rhomboclase; 16.46 per cent. sulphuric acid; and 40.81 per cent. of water yields römerite crystals. If the excess of sulphuric acid is not maintained, the soln. first deposits crystals of ferrous sulphate, then copiapite, and later rhomboclase.

Römerite varies in colour from light to dark chestnut-brown, violet-brown, rust-brown, and yellow. It occurs crystalline in coarse granules, and in tabular crystals parallel to (001); the habit may be monoclinic; and the (100)- and (001)-faces may be striated parallel to their edge of intersection, whilst the brachydome faces are vertically striated. The crystals are triclinic; G. Linck gave for the axial ratios $a : b : c = 0.96840 : 1 : 2.64250$, and $\alpha = 116^\circ 3\frac{1}{2}'$, $\beta = 94^\circ 40\frac{1}{2}'$, and $\gamma = 80^\circ 7\frac{1}{2}'$; J. Blaas, 0.8791 : 1 : 0.8475, and $\alpha = 89^\circ 44'$, $\beta = 102^\circ 17'$, and $\gamma = 85^\circ 18'$; and R. Scharizer gave 1.1751 : 1 : 0.8304, and $\alpha = 94^\circ 44'$, $\beta = 99^\circ 16'$, and $\gamma = 87^\circ 22'$. The (010)-cleavage is perfect; and, according to J. Grailich, the (100)-cleavage is less distinct. J. Grailich said that the pleochroism a is rose-red or rust-brown, b is colourless to rose-red, and c is pale or dark rust-brown. G. Linck gave a pale

yellowish-white, *b* darker yellowish-white, and *c* reddish-brown. The optical character is negative; the optic axial angle $2H_a=57^\circ 45'$ for Na-light; and the double refraction is small. E. S. Larsen found the index of refraction $\beta=1.87$; and R. E. Landon gave for the indices of refraction $\alpha=1.526$, $\beta=1.571$, and $\gamma=1.582$. J. Grailich gave 2.174 for the sp. gr., and G. Linck, 2.102; the hardness is 3.0 to 3.5. J. Grailich found that the crystals are diamagnetic. The salt is readily dissolved by water; the aq. soln. is acidic, and deposits basic salts when heated. According to R. Scharizer, when the aq. soln. of römerite is evaporated to dryness, the soln. decomposes in accord with the equation: $3\{\text{Fe}'''\text{Fe}_2''(\text{SO}_4)_4\} = 3\text{FeSO}_4 + 3\{\text{Fe}_2'''\text{SO}_4\}_3 = 3\text{FeSO}_4 + \text{Fe}_4'''\text{S}_5\text{O}_{18}(\text{copiapite}) + \text{Fe}_2'''\text{S}_4\text{O}_{15}(\text{rhomboclase})$. The presence of an excess of rhomboclase in the soln. does not prevent the decomposition of the römerite. A mixture of sulphuric acid (37.34 parts) and water (100 parts) dissolves 60.99 parts of römerite. The stability of a soln. of römerite is raised in the presence of rhomboclase, and it can exist in a soln. of sulphuric acid in the absence of rhomboclase. The solubility of römerite in a soln. of rhomboclase is very small. When römerite is exposed to moist air on a funnel, three-fifths of the original ferrous oxide present as ferrous sulphate remains on the funnel. R. Scharizer found a mineral in the Harz in which part of the ferrous iron is replaced by zinc—*vide supra*, zinc römerite.

C. Lausen found a mineral which he called **louderbackite**—after G. D. Louderback—occurring in pale, chestnut-brown, crystalline crusts in the mine at Jerome, Arizona, where the pyritic ore was smouldering for years; the crystals are biaxial, and have the composition of **ferrous ferric decasulphate**, $2\text{FeO} \cdot 3(\text{Fe}, \text{Al})_2\text{O}_3 \cdot 10\text{SO}_3 \cdot 35\text{H}_2\text{O}$. The sp. gr. is 2.185; the hardness is 2.5 to 3.0; the optical character is negative; and the indices of refraction are $\alpha=1.544$, $\beta=1.558$, and $\gamma=1.581$. C. Lausen also found under similar conditions, in the same locality, a mineral which he called **guildite**—after F. N. Guild. The chestnut-brown, monoclinic crystals had the composition of **copper ferrous ferric heptasulphate**, $3(\text{Cu}, \text{Fe})\text{O} \cdot 2(\text{Fe}, \text{Al})_2\text{O}_3 \cdot 7\text{SO}_3 \cdot 17\text{H}_2\text{O}$. The crystals have the axial ratios $a:b:c=1.037:1:1.407$, and $\alpha=74^\circ 43'$. The cleavages parallel to the base (001), and parallel to the front pinacoid (100), are both perfect. The optical character is positive. The sp. gr. is 2.725, and the hardness 2.5. The indices of refraction are $\alpha=1.623$, $\beta=1.630$, and $\gamma=1.684$. The birefringence is 0.061. The mineral is pleochroic with β and α pale yellow, and γ greenish-yellow.

J. A. Poumarède allowed a warm soln. of 2 parts each of hydrated ferrous and ferric sulphates, and 5 to 6 parts of water to crystallize, and obtained long, pale red needles of the **decahydrate**, $\text{FeSO}_4 \cdot \text{Fe}_2(\text{SO}_4)_3 \cdot 10\text{H}_2\text{O}$, which are very soluble in water. A. Étard obtained six-sided plates, the colour of peach-bloom, of **ferrous ferric tetrahydrohexasulphate**, $\text{FeSO}_4 \cdot \text{Fe}_2(\text{SO}_4)_3 \cdot 2\text{H}_2\text{SO}_4$, by dissolving eq. quantities of ferrous and ferric sulphates in as little water as possible, adding an excess of conc. sulphuric acid, and heating the mixture to about 200° ; and J. Lefort reported the **tridecahydrate**, $\text{FeSO}_4 \cdot \text{Fe}_2(\text{SO}_4)_3 \cdot 2\text{H}_2\text{SO}_4 \cdot 13\text{H}_2\text{O}$, to be formed when a cold soln. of hydrated ferrous oxide in conc. sulphuric acid is allowed to stand for some days, and the white salt separated from the mother-liquor on an asbestos-filter. The product is dissolved in the smallest possible quantity of cold water, and allowed to crystallize. The white salt is very deliquescent, but it is stable in dry air. It gives off water at about 75° , and decomposes at a high temp. into a mixture of ferrous and ferric oxides. H. Chandra could not verify this result. M. Lachaud and C. Lepierre added ferrous sulphate or ferrous ammonium sulphate to fused ammonium sulphate and insufficient sulphuric acid to convert all the ammonia to the hydrosulphate. The excess of ammonium sulphate is removed by treatment with alcohol. There remain colourless, prismatic needles of **ammonium ferrous ferric octosulphate**, $4(\text{NH}_4)_2\text{SO}_4 \cdot \text{FeSO}_4 \cdot \text{Fe}_2(\text{SO}_4)_3 \cdot 3\text{H}_2\text{O}$. The sp. gr. of the salt is 2.02 at -10° . It dissolves slowly in cold water, and is hydrolyzed into a basic sulphate by boiling water.

S. Breislak observed a dark green mineral at the solfatara near Naples, and it

was called **voltaite** by A. Scacchi. The same mineral was observed near Goslar in the Harz; in the cupriferous pyrites of Rio Tinto, Spain; in the pyritiferous trachyte of Madeni Zakh, in Persia; and at Kremnitz, and Schmöllnitz, in Hungary. Descriptions and analyses were reported by G. Tschermak, J. A. Krenner, H. F. Collins, C. A. Anderson, C. Lausen, J. Blaas, P. A. Dufrenoy, H. Abich, and R. Scharizer, and the results are difficult to represent by a single formula. B. Gössner and M. Arm represented it by: $K_2H_{10}(SO_4)_6 \cdot 3(Fe, Al)(OH)_3 \cdot 4FeSO_4 \cdot 4H_2O$. R. Scharizer was able to make the formula fit the analysis by assuming that there are two voltaites, one richer in bases than the other, each with 5 mols. of water of crystallization:

R. Scharizer concluded that natural and artificial voltaites are mixtures of a potassium salt of the acid $H_2Fe_2(SO_4)_4 \cdot 4 \cdot 33Aq.$, or $H_6Fe_6(SO_4)_{12} \cdot 13Aq.$ and the acid $H_{12}Fe_4(SO_4)_{12} \cdot 18Aq.$ B. Gössner and E. Fell gave the general formula: $Fe_4'''R_5''R_2'(SO_4)_{12} \cdot 16$ to $18H_2O$. The dehydration curve shows that the loss of water commences at 200° ; there is a break at 200° when about 7 mols. of water are lost. The losses with two samples were:

	170°	190°	200°	220°	240°	270°	280°	350°	440°
Loss	0.07	0.31	5.84	6.24	7.50	11.59	12.04	12.80	15.09 per cent.

B. Gössner and M. Arm obtained the following losses (time in hours in brackets):

	100° (20)	150° (30)	200° (40)	225° (50)	300° (60)
Loss	0.70	0.85	1.6	5.3	13.9 per cent.

so that at 200° , the crystals appear turbid; and the water is expelled above this temp. They consider that the water is mainly present as water of crystallization, and represent the formula: $K_2H_4(SO_4)_3 \cdot 3Fe(OH)(SO_4) \cdot 4FeSO_4 \cdot 10H_2O$. B. Gössner and T. Bäuerlin gave: $[KH_5(SO_4)_3]_2[(Fe, Al)(OH)_3][FeSO_4]_4 \cdot 4H_2O$.

H. Abich obtained a salt resembling voltaite, $3FeSO_4 \cdot 2Fe_2(SO_4)_3 \cdot 12H_2O$, by boiling a mixture of a not too dilute soln. of 16 parts of ferrous sulphate with 1 part sulphuric acid of sp. gr. 1.4, then adding a hot, conc. soln. of 5 to 6 parts of ferric alum, and evaporating the liquid at 87° . A soln. of the powder in acidulated water was evaporated on a water-bath. L. C. A. Barreswil treated a sat. soln. of ferrous sulphate which was oxidized by adding a mixture of sulphuric and nitric acids, and then treated with conc. sulphuric acid without allowing the temp. to rise. A deep blue precipitate is formed which is decomposed by water. J. Blaas, and R. Scharizer obtained voltaite by crystallization from a soln. of its constituent salts containing an excess of sulphuric acid. B. Gössner and co-workers prepared voltaite by mixing 300 c.c. of water and 45 c.c. of sulphuric acid with 60.4 grms. of $FeSO_4 \cdot 7H_2O$, and 6.7 grms. of potassium sulphate together with varying proportions of 39.1 to 84.5 grms. $Al_2(SO_4)_3 \cdot 18H_2O$, and 28.5 to 2.5 grms. $Fe_2(SO_4)_3$, and keeping the liquid at 80° for some days on a sand-bath. The colour of the soln. is first brown, and when sulphuric acid is added, almost black. As the voltaite separates, the mother-liquor becomes almost colourless. If the soln. is kept at ordinary temp., separations other than voltaite occur; and other products are obtained at higher temp., or with soln. containing more than 30 grms. of ferric sulphate, and less than 30 grms. of aluminium sulphate, or with less than 2.5 grms. of ferric sulphate and over 85 grms. of aluminium sulphate. No voltaite was obtained if either the aluminium or the ferric sulphate be omitted altogether. If chromic sulphate be used in place of ferric sulphate, no **chromic voltaite** was formed; nor was a **nickel voltaite** obtained by using nickelous sulphate in place of ferrous sulphate; but with manganous sulphate in place of ferrous sulphate, orange-yellow cubic crystals of **manganese voltaite**, $2KHSO_4 \cdot 4H_2SO_4 \cdot 4MnSO_4 \cdot 3Fe(OH)_3 \cdot 4H_2O$, of sp. gr. 2.62, were formed; and

with cobaltous sulphate, in place of ferrous sulphate, dark red, cubic crystals of **cobalt voltaite**, $2\text{KHSO}_4 \cdot 4\text{H}_2\text{SO}_4 \cdot 4\text{CoSO}_4 \cdot 3\text{Fe}(\text{OH})_3 \cdot 4\text{H}_2\text{O}$, of sp. gr. 2.65, were formed. B. Gössner and co-workers obtained a series of voltaites with the iron partly replaced by alumina and containing as bases **thallium ferrous voltaite**, in octahedral, bluish-green crystals of sp. gr. 3.06 to 3.09; **thallium magnesium voltaite**, in cubic—dodecahedra—green crystals of sp. gr. 2.803; **thallium cadmium voltaite**, in cubic—octahedral and dodecahedral—pale green crystals; **rubidium cadmium voltaite**, in cubic, green crystals of sp. gr. 2.990; and **ammonium magnesium voltaite**, in small, green, cubic crystals of sp. gr. 2.375.

Voltaite occurs in dull green, greenish-black, brown, or black cubic octahedral or dodecahedral crystals, or in combinations of these forms belonging to the cubic system. B. Gössner and M. Arm found that the black, cubic crystals of octahedral habit furnish X-radiograms corresponding with a unit cell having the parameter $a=27.33 \text{ \AA}$., and containing 20 mols. The sp. gr. is 2.79; C. A. Anderson gave 2.75; C. Lausen, 2.611; and B. Gössner and M. Arm, 2.648 to 2.654; and the hardness 3 to 4. The double refraction is strong; E. S. Larsen found the index of refraction to be 1.602; C. A. Anderson gave 1.604; and C. Lausen, 1.594. There is no pleochroism. Voltaite is sparingly soluble in water, and the aq. soln. deposits crystals of metavoltine, but in the presence of free sulphuric acid, sphæro-crystals, and composite pseudo-cubic crystals of voltaite are deposited.

A. Paulinyi described a mineral which he called *pettkoite*—after B. von Pettko—and which he obtained from Kremnitz, Hungary, but G. Tschermak showed that it is the same mineral species as voltaite. S. Singer described lemon-yellow, microscopic, monoclinic or triclinic, prismatic crystals of the composition $(\text{K}, \text{Na})_2\text{O} \cdot 2\text{FeO} \cdot 3(\text{Al}, \text{Fe})_2\text{O}_3 \cdot 6\text{SO}_3 \cdot 27\text{H}_2\text{O}$, occurring at Bauersberg, near Bischofsheim. He called the mineral *plagiocitrite*. The sp. gr. is 1.881. It decomposes on exposure to air, becoming reddish-yellow; it is soluble in water and the soln. has an acidic reaction and deposits hydrated ferric oxide on boiling. Greenish-black, microscopic, probably monoclinic crystals of the composition $4(\text{K}, \text{Na})_2\text{O} \cdot \text{FeO} \cdot (\text{Fe}, \text{Al})_2\text{O}_3 \cdot 5\text{SO}_3 \cdot 8\text{H}_2\text{O}$, were found in the same locality. The mineral was called *clinophæite*. Its sp. gr. is 2.979. It dissolves in water with difficulty, and when the soln. is boiled it deposits hydrated ferric oxide. A deep saffron-yellow mineral occurring in the same locality was called *clinoerocite*. The crystals are probably monoclinic, and a qualitative analysis shows that it belongs to this family of salts. A. Schrauf observed a yellowish-grey, compact or crystalline sulphate related to botryogen in the mercury mines of India, Carniola, and he called it *idrizite*. The analysis corresponds with **magnesium ferrous ferric trisulphate**, $(\text{Mg}, \text{Fe})\text{O} \cdot (\text{Al}, \text{Fe})_2\text{O}_3 \cdot 3\text{SO}_3 \cdot 16\text{H}_2\text{O}$. Unlike quetenite, it is insoluble in hot and cold water.

P. C. Ray and P. B. Sarkar prepared the salt **ammonium ferric sulphatofluoberyllate**, $(\text{NH}_4)_2\text{BeF}_4 \cdot \text{Fe}_2(\text{SO}_4)_3 \cdot 24\text{H}_2\text{O}$, isomorphous with the alums. The salt was discussed by W. R. C. Curzel, and H. Seifert. N. Bjerrum and G. H. Hansen prepared from ferric sulphate and the chromic dibromotetraaquesulphate, a complex **ferric chromic bromosulphate**, $[\text{CrBr}_2(\text{H}_2\text{O})_4][\text{Fe}(\text{H}_2\text{O})_6](\text{SO}_4)_2 \cdot 2\text{H}_2\text{O}$, but the corresponding chloro-compound could not be prepared.

§ 48. The Iron Carbonates

The early writers referred to a mineral under various terms; thus, in 1565, C. Gesner¹ called it *stahelreich Eisen*; in 1735, C. Linnæus, *ferrum intractibile albicans spathosum*; in 1747, J. G. Wallerius, *minera ferri alba spathiformis*; A. Cronstedt, *Zarn med Kalkjord förenadt*; T. Bergmann, *ferrum cum magnesio et terra calcarea acido aereo mineralisatum*; J. B. L. Romé de l'Isle, *fer spatique*—hence the term *spathic iron ore*; R. Kirwan, *calcareous or sparry iron ore*; J. F. L. Hausmann, *Eisenspath*, and also *spherosiderite*; F. S. Beudant, *siderose*; P. A. Dufrénoy, and A. Breithaupt, *junckérite*—after M. Junckér; E. F. Glocker, *chalybite*; and W. Haidinger, *siderite* for the mineral, from W. Haidinger's term *spherosiderite*. W. Haidinger reserved the latter name for a concretionary variety. F. Slavik discussed the *spherosiderite* of Kirvinna, Silesia; and C. Y. Hsieh, those of the cretaceous coal of China. Some varieties of *siderite* have received special terms. Thus, A. Breithaupt applied the term *oligonspath*, a manganiferous variety, and J. F. L. Hausmann shortened the word to *oligonite*; A. Mayer called a variety from Bleisbach, Siebengebirge, *thomäite*—after K. Thomä; and a magnesium variety, *sideroplesite*. A variety from New Zealand was called *pelosiderite* by F. Zirkel. Impure siliceous and argillaceous varieties are sometimes called *clay ironstone*, or the *black band ores* of the coal measures. The term *spherosiderite* is applied to a variety which occurs in more or less rounded spherules. J. Young observed a variety from Campsie, Scotland, in which the spherules averaged one-

sixteenth of an inch in diameter, and in section they showed layers of ferrous carbonate round a spherical centre in various shades of brown; they also show a radiating crystalline structure.

In 1774, P. Bayen² showed that when the mineral is treated with an acid, it gives off a gas, carbon dioxide, and that lime is present in the acid soln.; he also thought that zinc was present. T. Bergman, and B. G. Sage detected manganese in some samples. In 1804, C. F. Bucholz found 59.5 per cent. of ferrous oxide, and 2.5 per cent. of calcium oxide but not manganese. He noted that a gas is given off when the mineral is heated, and that the residue exhibits polar magnetism. In 1806, H. V. Collet-Descotils reported many analyses, and noted the variations in the composition of the mineral. In 1807, C. F. Bucholz and M. H. Klaproth obtained similar results. Analyses reported by C. F. Rammelsberg,³ C. R. von Hauer and C. von John, K. R. von Hauer, C. von John, H. von Foullon, F. Sandberger, G. Grattarola, A. Brunlechner, G. H. Williams, F. Beyschlag, A. von Elterlin, G. Bodländer, H. Schwager and C. W. von Gümbel, W. Ortloff, F. Gervais, E. Manasse, F. Gonnard, A. Hutchinson, P. A. Dufrénoy, H. How, E. V. Shannan, C. F. Eichleiter, F. Kretschmer, K. A. Redlich, L. Dürr, A. Carnot, A. Gesell, A. Miko, B. Tacke, A. Pattera, F. Seeland, T. G. Clemson, W. F. Hillebrand, M. Ungemach, L. Girolami, J. von Schröckinger, W. T. Schaller, C. Klein, A. Lasard, A. Frenzel, F. Mons, A. Lévy, L. Colomba, R. P. Greg and W. G. Lettsom, A. Russell, C. Palache, V. R. von Zepharovich, F. W. Clarke, D. Stur, S. Nikitin, W. Michailowsky, C. J. B. Karsten, P. Berthier, J. P. J. Monheim, J. Fritsche, E. Glasson, C. Schnabel, H. Vorl, B. Baumgärtel, G. Bischof, S. P. Popoff, L. Dürr, G. A. Kenngott, A. Pleischl, W. Ortloff, W. Heyer, O. Luedecke, A. Sigmund, G. Magnus, P. Poni, S. G. Rosengarten, D. P. McDonald, M. F. Heddle, A. Lacroix, and F. Tucan. The results in the minerals of a high degree of purity correspond with **ferrous carbonate**, FeCO_3 . G. Bodländer noted a sample from Neunkirchen, Siegen, with 3.85 per cent. of cobalt; and W. N. Hartley and H. Ramage, samples of Yorkshire clay ironstone with gallium.

Siderite occurs in crystals which are commonly rhombohedral, with the faces more or less curved and built up of smaller crystals. The mineral may also occur in cleavable masses, it may be sub-fibrous or it may occur in silky fibres. It may occur in coarse-grained or fine-grained masses, or in concretionary—botryoidal or globular—forms—e.g., J. F. L. Hausmann's sphaeroiderite—and it may have a scaly or fibrous structure. It may appear oolitic like oolitic limestone; and it may be compact and earthy owing to associated clay or sand as in clay ironstone. The colour is rarely white, and it may appear to be ash-grey, yellowish-grey, greenish-grey, grey, brown, brownish-red, pink, and, in rare cases, green. The colour is produced by impurities. Besides ferrous carbonate of a high degree of purity, one group of siderites may contain several per cent. of manganese carbonate—*manganese siderites*—and the colour has then a yellowish tinge or it may be flesh-red or iron-red; another group may contain several per cent. of magnesium carbonate—*magnesium siderites*—and very little manganese carbonate; another group may contain as much as 20 per cent. of calcium carbonate—*calciferous siderites*; and yet another may contain relatively large proportions of both calcium and magnesium carbonates—*dolomitic siderites*. The iron, calcium, magnesium, and manganese carbonates are isomorphous, and miscible in all proportions, so that the siderites may pass into ferruginous calcespar, ferruginous rhodochrosite, and ferruginous magnesite—e.g., a ferruginous dolomite is called ankerite. *Boxwork siderite*, so named from its structure and appearance, was described by Y. S. Bonillas and co-workers, and by C. Trischka and co-workers.

It was shown in connection with limonite, and bog-iron ores, that waters carrying iron salts in the presence of much carbonic acid, or decaying organic matter, deposit the iron in the form of siderite, and if the conditions are such that air has free access, limonite may be formed. In some cases the deposition is effected by the so-called iron bacteria. If the iron carbonate is deposited from muddy

waters, salt will be associated with the carbonate, and clay ironstone, or black band ores will be formed. This subject has been discussed by F. M. Stappf,⁴ E. Kohler, H. Sjögren, K. A. Redlich, J. S. Newberry, A. von Schouppe, J. H. L. Vogt, J. W. Gruner, H. Bücking, W. Reinders, B. Baumgärtel, B. Tacke, A. Gärtner, J. Beyschlag, E. J. Moore, R. Canaval, J. M. van Bemmelen, C. L. Dake, A. Brunlechner, and G. R. van Hise. Siderite may also be formed by an exchange of bases when soln. of iron salts act on limestones, or other carbonate rocks. H. C. Sorby, J. P. Kimball, and L. Dieulafait showed that this may occur by the action of ferrous sulphate soln. on calcium carbonate; while H. C. Sorby, G. Keller, J. N. von Fuchs, J. von Kobell, and H. Demarçay showed that with soln. of ferric sulphate, hydrated ferric oxide is precipitated. J. M. van Bemmelen added that in some cases the deposit which is formed is **colloidal ferrous carbonate**—e.g., the siderite in the peat of the moors in the south-east of Drenthe, Holland. This subject was also discussed by W. Reinders, and A. Gärtner. R. J. Hartman and co-workers obtained periodic precipitations of ferrous carbonate.

In illustration of the formation of siderite in nature, J. R. Blum⁵ described pseudomorphs of siderite after galena; H. A. Miers, pseudomorphs after bismuth glance; J. R. Blum, and R. P. Greg and W. G. Lettsom, after fluorite; J. R. Blum, A. Frenzel, G. Greim, F. Gonnard, after calcite; J. R. Blum, after dolomite; J. R. Blum, G. Greim, and A. Frenzel, after aragonite; J. R. Blum, and R. P. Greg and W. G. Lettsom, after barytes; and J. H. Collins, after gypsum.

The formation and preparation of ferrous carbonate.—When a soln. of a ferrous salt is treated with an alkali carbonate, a white hydrated ferrous carbonate is precipitated. On exposure to air, the precipitate soon acquires a green colour, and it afterwards becomes brown, owing to oxidation. Alkali hydrocarbonates furnish a similar precipitate with soln. of ferrous sulphate provided that the soln. are not too dilute. If they are dilute, some ferrous salt is retained in solution, but is deposited when the soln. are boiled. It is difficult to wash and dry the precipitate without oxidation. The preparation of the carbonate by these methods has been discussed by F. Arcularius,⁶ C. Birkholz, W. Petrascheck, L. Bley, C. H. Bolle, R. Brandes, E. Braun, A. Buchner, C. F. Bucholz and J. W. Döbereiner, M. Daum, F. Fölix, P. Groth, H. Hager, G. A. Kennigott, C. Klauer, A. Lacroix, A. Meillet, C. F. Mohr, H. Reinsch, W. T. Schaller, F. W. Schmidt, G. Schmidt, A. G. Vallet, H. Wilkens, and G. C. Wittstein. R. E. Brewer and G. H. Montillon precipitated ferrous carbonate by adding sodium carbonate to a soln. of ammonium ferrous sulphate in an atm. of hydrogen; washed the white or greenish-white precipitate with water saturated with hydrogen; and preserved the product under water similarly treated. The yield was smaller when sodium hydrocarbonate was the precipitating agent. H. J. Smith obtained a white carbonate by placing equimolar proportions of solid ferrous sulphate and sodium hydrocarbonate in a steel bottle, and displacing the air by carbon dioxide. Water saturated with carbon dioxide was added, and the bottle closed by a plug attached by a suitable valve to a cylinder of compressed carbon dioxide. The valve was closed when the press. in the bottle had attained 400 lbs. and the bottle was kept at 100° for several days. The precipitate was filtered in an atm. of carbon dioxide, and washed with water sat. with carbon dioxide. A similar process was employed by A. Meillet. The analyses of J. B. Berthemot, H. Diesel, F. J. Malaguti, G. Schmidt, H. Schütte, B. Tacke, G. C. Wittstein, and F. Massieu show that water is only mechanically associated with precipitated ferrous carbonate; no definite hydrate has been prepared. R. C. Wells discussed the fractional precipitation of ferrous carbonate from soln. of ferrous salts mixed with salts of copper, calcium, zinc, cadmium, lead, and nickel. H. de Sénarmont heated a soln. of ferrous sulphate with sodium carbonate in a sealed tube 150° or over, or else a mixture of ferrous chloride and calcium carbonate at 135° to 180°, for 12 to 18 hrs., and obtained a greyish-white, arenaceous material which consisted of crystals of siderite. A. Buchner previously prepared ferrous carbonate by the action of powdered calcite on a soln. of ferrous chloride in a sealed

tube; and F. Hoppe-Seyler heated to 200° a soln. of ferrous sulphate with an excess of calcium carbonate in a tube from which oxygen had been displaced, and obtained microscopic crystals of siderite. A. Bruzs found that the ferrous carbonate prepared by H. de Sénarmont's process loses 20 per cent. of its carbon dioxide when it is dried. As indicated above, H. C. Sorby, and others have observed that when calcite, aragonite, or witherite is immersed in a sealed tube at 100° to 150° , there is a slow exchange of bases, so that in about a month, crystals of siderite are formed. The formation of ferrous carbonate by rusting iron was discussed by F. C. Calvert, and G. T. Moody—*vide supra*.

A. Meillet obtained white, compact ferrous carbonate by the action under press. of carbon dioxide on precipitated ferrous carbonate containing more or less ferrous hydroxide. F. K. Cameron and W. O. Robinson observed that at 0° , and under a press. of 76 to 274 cm., carbon dioxide converts moist ferrous hydroxide into carbonate, but not into hydrocarbonate—*vide infra*. P. N. Raikow passed carbon dioxide into water with freshly-precipitated ferrous hydroxide in suspension, and found that 13 to 22 per cent. more carbon dioxide was absorbed than is necessary for the formation of ferrous carbonate. A. Smits, and W. P. Jorissen and J. Rutten observed that ferrous sulphide is slowly transformed by carbon dioxide into ferrous carbonate. J. Durochet, and R. Brauns described the formation of crystals of siderite by the action of the vapour of ferrous chloride on ammonium carbonate in an iron tube at a red-heat.

L. Bourgeois failed to obtain ferrous carbonate by heating a ferrous salt soln. with urea at about 140° . A. Michaelis obtained ferrous carbonate by boiling ferrous oxalate with a soln. of potassium hydrocarbonate; and V. Volmar, by the action of ultra-violet light on a 1 per cent. soln. of ferric tartrate—the ferrous carbonate was mixed with ferrous hydroxide. F. Haber and F. Goldschmidt electrolyzed soln. of potassium, sodium, and calcium hydrocarbonates between iron electrodes with a diaphragm-cell, at 20° , and obtained in the anode compartment greyish-white ferrous carbonate.

A. Flüge obtained ferrous carbonate for medicinal purposes by triturating a cold mixture of alkali hydrocarbonate and ferrous sulphate with glycerol or a sugar soln.: $\text{FeSO}_4 + 2\text{KHCO}_3 = \text{FeCO}_3 + \text{K}_2\text{SO}_4 + \text{H}_2\text{O} + \text{CO}_2$. Other processes for obtaining an analogous product were described by O. Anselmino and E. Gilg, M. Tennenbaum and C. von Eweye, and J. C. Krantz. The object is to retard the oxidation of the ferrous carbonate in air—*vide infra*.

The physical properties of ferrous carbonate.—The colour of ferrous carbonate is white, but by oxidation it acquires a green tinge and later becomes brown. Siderite may occur in nature, white, ash-grey, green, greenish-grey, yellowish-grey, brown, and brownish-red. The powder is white. Siderite occurs crystalline; in cleavable, fine or coarse granular masses; in botryoidal and globular forms with a sub-fibrous or silky fibrous structure; and in compact or earthy masses. The crystals are commonly rhombohedral, and their faces are often curved and built up of sub-individuals. W. H. Wollaston gave for the axial ratio of siderite $a : c = 1 : 0.81841$; A. Breithaupt gave $1 : 0.8191$ and $\alpha = 103^{\circ} 41'$; and E. Mitscherlich gave $a : c = 1 : 0.81840$ at ordinary temp., and $1 : 0.81912$ at 100° . F. Rinne found that the angle α changes $3.1'$ per 100° rise of temp. so that for the normal angle, at :

	-165°	60°	22°	104°	200°	302°	385°
α	$72^{\circ} 59' 51''$	$73^{\circ} 3' 7''$	$73^{\circ} 3' 50''$	$73^{\circ} 6' 42''$	$73^{\circ} 10' 1''$	$72^{\circ} 13' 41''$	$72^{\circ} 16' 46''$

The value of $a : c$ at -165° is $1 : 0.8184$; at 22° , $1 : 0.8194$; and at 385° , $1 : 0.8235$. Observations on the crystals were made by A. Breithaupt, G. Cesaro, A. des Cloizeaux, L. Colomba, V. Goldschmidt, M. Henglein, G. A. Kennigott, C. Klein, A. de Klerk and V. Goldschmidt, W. Jansen, A. Lacroix, A. Lévy, E. Manasse, W. H. Miller, C. Palache, A. Russell, W. T. Schaller, and L. J. Spencer. Siderite is uniaxial, but A. Madelung observed a sample from Neudorf, Harz, which was feebly

biaxial. Siderite belongs to an **isomorphous family**, $R''CO_3$, where **R** may denote Ca, Sr, Ba, Mg, Zn, Pb, Mn, Fe, and Co. The isomorphism was discussed by G. Bilibin, P. Gaubert, W. Diesel, K. Grünberg, and H. de Sénarmont. This is exemplified by the minerals *bräunerite*, *roepperite*, *masitite*, and *sideroplesite*, $(Mg,Fe)CO_3$; *manganocalcite*, and *spartoite*, $(Ca,Mn,Fe,Mg)CO_3$; *rhodochrosite*, *manganese spar*, and *dialogite*, $(MnFe)CO_3$; *iron zinc spar*, $(Zn,Fe)CO_3$; *monheimite*, $(Zn,Mn,Fe)CO_3$; and *ankerite*, $(Ca,Mg,Fe)CO_3$. W. Diesel observed solid soln. of ferrous and calcium carbonates of the vaterite type, and hence H. E. Boeke inferred that there is an unstable modification of ferrous carbonate which has not yet been isolated, and whose sp. gr., by extrapolation, is near 3.4. The colloidal form has been indicated above. The **twinning** of the rhombohedral crystals occurs about the (01 $\bar{1}$ 2)-plane, often with enclosed twinning lamellæ; the subject was discussed by E. Ammermann, G. A. Kenngott, and L. J. Spencer. The (0001) **cleavage** is perfect. A. Johnsen found that, as with calcite, the (10 $\bar{1}$ 1)-plane is a **gliding plane**. The **corrosion figures** are in part symmetric and in part asymmetric, and they were examined by H. Baumhauer, A. P. Honess, W. T. Schaller, and G. Tschermak. I. N. Stransky and K. Kubelief studied the **growth of the crystals**; P. Groth, parallel **over-growths** with calcite, and S. Kreutz, over-growths with lithium nitrate. The **X-radiograms** of siderite were investigated by W. Jansen, W. L. Bragg and co-workers, P. P. Ewald, and P. Niggli. According to R. W. G. Wyckoff, the elementary rhombohedral cell has the parameter $a=6.04$ Å, $\alpha=47^\circ 46'$; G. Natta: $a=5.82$, and $\alpha=47^\circ 45'$; and P. Niggli calculated that there are 4 mols. per cell. the edge of the cell is 5.94×10^{-8} to 5.99×10^{-8} cm., the vol. of the cell is 194.9×10^{-24} c.c., and the vol. of the mol. $FeCO_3$ is 48.75×10^{-24} c.c. The structure of the CO_3 -group was discussed by C. Schaefer and co-workers, and J. E. Lennard-Jones and B. M. Dent; the arrangement of the electrons, by M. L. Huggins; the structure of the lattice by W. L. Bragg and S. Chapman, and S. Chapman and co-workers; the free energy of formation of the crystals from the elements, by J. L. Buchan; and the work of separating Fe^{++} from CO_3^{--} -ions, by J. E. Lennard-Jones and B. M. Dent. P. Niggli studied the **electronic structure**.

The **specific gravity** of pure siderite, extrapolated by E. T. Wherry and E. S. Larson, is 3.96; W. E. Ford gave 3.633 to 3.951 for samples of siderite with 78.2 to 95.9 per cent. $FeCO_3$; H. Kopp gave 3.796 at 0° ; P. A. Dufrenoy, 3.815; N. Sundius, 3.927; A. Breithaupt, 3.698; F. E. Neumann, 3.872; A. Hutchinson, 3.936 to 3.938; A. Lemke and W. Biltz, 3.832 to 3.856; and E. Madelung and R. Fuchs, 3.7718. The effect of impurities is shown in Table XCV by P. Niggli; K. Grünberg's curve for the sp. gr. of mixtures of ferrous and calcium carbonates is shown in Fig. 679. I. I. Saslawsky calculated a value for the contraction which occurs when ferrous carbonate is formed from its elements. A. Lemke and W. Biltz studied this subject. The **hardness** of siderite on Mohs' scale is 3.5 to 4. F. Pfaff found that if the hardness of talc be unity, that of siderite on the (0001)-face is 32, and on the (10 $\bar{1}$ 1)-face, 53. E. Madelung and R. Fuchs gave 0.0699 for the coeff. of **compressibility** in megabars per sq. cm. L. H. Adams and E. D. Williamson gave $\beta=0.0660$; and for the **bulk modulus**, $K \times 10^{-6}=1.67$; and the **rigidity**, $R \times 10^{-6}=0.91$.

H. Fizeau found the coeff. of **thermal expansion** in the direction of the a -axis to be 0.00001918, and perpendicular to that axis, viz. the c -axis, 0.00000605, at 40° . F. Pfaff gave 0.000005388 for the c -axis, and 0.000016133 for the a -axis from 0° to 100° . For the coeff. of cubical expansion, H. Kopp gave 0.000035 between 14° and 45° ; and F. Pfaff, 0.00002688 between 0° and 100° . Observations were made by O. Hülsmann and W. Biltz. E. Jannettaz gave 1.06 for the sq. root of the ratio of the **thermal conductivity** parallel and vertical to the chief axes. F. E. Neumann

FIG. 679.—The Specific Gravities of Solid Soln. of Calcium and Ferrous Carbonates.

found the **specific heat** of siderite to be 0.182 to 0.183; H. Kopp gave 0.166 between 17° and 46°; H. V. Regnault, 0.1934 between 9° and 98°; and F. Ulrich and E. Wollny, 0.1793. C. Pape made some observations on H. V. Regnault's results. W. A. Roth and W. Bertram found the mean sp. ht. between 20.5° and 95° to be 0.196; and the mean molecular heat, 22.72 at 100°. C. T. Anderson gave for C_p at

	-218.9°	-205.6°	-182.2°	-141.2°	-89.0°	-32.6°	13.0°	23.3°
C_p	4.117	5.714	8.489	12.14	15.15	17.83	19.34	19.57

At the beginning of the nineteenth century, C. F. Bucholz, and M. H. Klaproth noted that the **thermal decomposition** of siderite at a red-heat, and out of contact with air, results in the evolution of a combustible gas, presumably carbon monoxide, and the residual oxide is magnetic, presumably Fe_3O_4 . The carbon monoxide is formed by the reduction of carbon dioxide by ferrous oxide at a red-heat. This was confirmed by the work of J. W. Döbereiner, J. N. von Fuchs, F. J. Malaguti, A. Krämer, E. Glasson, S. de Luca, and I. L. Bell. J. W. Döbereiner gave $5\text{FeCO}_3 = 3\text{FeO} + \text{Fe}_2\text{O}_3 + 4\text{CO}_2 + \text{CO}$. J. A. Hedvall observed that with 4 hrs. heating at 700°, a basic ferrous carbonate gave ferric oxide. K. Busz, W. Jung, J. J. Nöggerath, and H. Pohligh also observed that siderite appears to have been converted into magnetite when it has been in contact with basalt intrusions. G. C. Wittstein observed that when hydrated ferrous carbonate is heated out of contact with air, the ferrosic oxide which is formed may be pyrophoric. H. Moissan observed that ferrosic oxide is formed when ferrous carbonate is heated out of contact with air, and when carbon dioxide is passed over ferrous oxide, carbon monoxide and ferrosic oxide are formed. Hence it is probable that the ferrous carbonate first splits into ferrous oxide and carbon dioxide, and that these react on one another in accord with: $2\text{FeO} + \text{CO}_2 = \text{CO} + \text{Fe}_2\text{O}_3$. If ferrous carbonate be slowly heated in a current of nitrogen, ferrosic oxide is produced, and if rapidly heated, pyrophoric ferrous oxide is formed.

A. Knop observed that the thermal decomposition of ferrous carbonate begins at about 350°. K. Friedrich and L. G. Smith found that the decomposition of siderite begins at about 400°, and proceeds rapidly at 460° to 500°. H. Wöbling said that the decomposition begins at about 220°, but only becomes appreciable at about 300°; the reaction is favourably influenced by water vapour; W. Hempel and C. Schubert, that the reaction begins at 470°, and is completed at 880°; J. A. Hedvall, that in nitrogen, siderite begins to decompose at 195°; H. Schneiderhöhn, that the decomposition is perceptible between 300° and 400°; and A. Gautier and P. Clausmann that siderite slowly decomposes at 300°, and rapidly at 400° in accord with: $3\text{FeCO}_3 = \text{Fe}_3\text{O}_4 + 2\text{CO}_2 + \text{CO}$. E. A. Wülfing observed that siderite of a high degree of purity lost 31.71 per cent. in weight on heating it 2 hrs. at 500°, and 32.61 per cent. when heated for 10 mins. over a blast-flame. F. Duftschmidt observed that the reactions which occur in an inert gas can be symbolized: $\text{FeCO}_3 = \text{FeO} + \text{CO}_2$ and $3\text{FeO} + \text{CO}_2 = \text{Fe}_3\text{O}_4 + \text{CO}$. In a current of carbon dioxide mixed with nitrogen, when the partial press. of the carbon dioxide is 710 mm., siderite begins to decompose at about 450°; the speed of the reaction rapidly rises with the temp.; in nitrogen alone, the mineral darkens at 300°, and at 350° the evolution of carbon dioxide is perceptible. Air accelerates the decomposition more than does nitrogen. In a current of carbon dioxide, ferrosic oxide is produced at 550°, and at higher temp. ferric oxide is formed. In a current of air ferric oxide is produced. H. Fleissner added that in steam, the ferrous carbonate decomposes at 250°, in air at 420°, in nitrogen at 440°, and in carbon dioxide at 500°. L. Gruner studied the decomposition of the carbonate in carbon dioxide; and H. Fleissner and F. Duftschmidt, in carbon monoxide, producer gas, and hydrogen. According to B. Bruzs, the thermal decomposition of siderite in the interval 491° to 581° is unimolecular, $dx/dt = ae^{-kt}$, where a is the initial velocity when $t=0$; and k is the velocity constant:

	491°	511°	521°	531°	541°	550°	561°	573°	581°
k	0.00805	0.0221	0.0442	0.0851	0.191	0.352	0.607	0.989	1.472

The velocity constant is abnormal at 491° , and between 445° and 495° , the velocities are low. It is inferred that within this range, the velocity constant remains unchanged, whilst the active mass increases with temp. Whilst the mineral form can be completely decomposed at 495° , the synthetic form can be decomposed at 340° —when the press. of carbon dioxide is 760 mm. The values of k are 0.0110 at 340° , 0.0152 at 350° , and 0.0239 at 360° . The critical increment, E , calculated from $\log(k_1/k_2) = (E/R)(T_2^{-1} - T_1^{-1})$, is 85,500 cal. for siderite between 501° and 561° , and 30,700 cal. for the synthetic carbonate between 340° and 360° . The influence of the grain-size of the carbonate on the speed of decomposition was examined by H. Fleissner, and B. Bruzs; and W. A. Noyes and W. E. Vaughan, and K. Fischbeck and K. Schnaidt discussed the reaction.

M. Berthelot calculated for the **heat of formation** of precipitated ferrous carbonate, $(\text{Fe}, \text{C}, 1\frac{1}{2}\text{O}_2) = 178.8$ Cals.; H. le Chatelier gave for the crystallized carbonate, 184.5 Cals.; and with carbon as graphite, W. A. Roth and co-workers gave 171.7 Cals. H. le Chatelier also gave for the crystalline carbonate and gaseous carbon dioxide, $(\text{FeO}, \text{CO}_2) = 25.2$ Cals., and W. A. Roth, and D. Müller 13.4 Cals. Values were also calculated for the thermal decomposition by B. Bruzs—*vide supra*. M. Berthelot gave for the **heat of neutralization** with dissolved carbon dioxide, $\{\text{Fe}(\text{OH})_2, \text{CO}_2\} = 10.0$ Cals., and with gaseous carbon dioxide, 15.6 Cals. W. A. Roth found that the **heat of oxidation**: $3\text{FeCO}_3 + \frac{1}{2}\text{O}_2 = \text{Fe}_3\text{O}_4 + 3\text{CO}_2 + 33.4$ Cals. J. L. Buchan gave $-175,000$ cal. per mol for the **free energy** calculated from the heat of formation of the crystalline carbonate from its elements; and $-151,520$ cal. per mol when calculated from the lattice constants. C. T. Anderson gave 22.2 for the **entropy**. J. E. Lennard-Jones and B. M. Dent calculated the work of separating Fe^{++} -ions from CO_3^{--} -ions in the crystal lattice to be 759 to 765 cal. per mol.

A. Hutchinson found that the **indices of refraction** of siderite from Camborne, Cornwall, with respectively 98.43, 1.82, 0.18, and 0.26 per cent. of ferrous, manganese, calcium, and magnesium carbonates, to be:

	Li-	Na-	Tl-light
ω	1.8642 to 1.8655	1.8722 to 1.8734	1.8798 to 1.8812
ϵ	1.6278 to 1.6306	1.6310 to 1.6342	1.6344 to 1.6373

W. Orloff observed a pale yellow siderite from Wolfsberg, Harz, to have $\omega = 1.93409$, and $\epsilon = 1.62185$. The results of W. E. Ford, H. von Philipsborn, P. Gaubert, and E. T. Wherry and E. S. Larsen were collected by P. Niggli in Table XCV.

TABLE XCV.—INDICES OF REFRACTION AND SPECIFIC GRAVITIES OF SIDERITES.

W. E. Ford's results are marked *, and those of P. Gaubert **. Observations were also made by N. Sundius, and W. A. Wooster. By extrapolation, E. T. Wherry

and E. S. Larsen found that for ferrous carbonate, $\omega=1.875$, and $\epsilon=1.635$; and W. E. Ford, $\omega=1.875$ and $\epsilon=1.633$. W. L. Bragg calculated for the molecular refraction, 13.48 from ω and 10.57 from ϵ . S. Procopiu found that powdered siderite suspended in organic liquids, exhibits **double refraction** in magnetic and electric fields. The double refraction of abnormal crystals, observed by A. Madelung has been previously mentioned. J. Chaudier also found that suspensions of powdered siderite in carbon disulphide exhibit an optical and an electrical birefringence.

L. B. Morse measured the **reflecting power** of the crystals for ultra-red light between 5μ and 16μ , and maxima were found for 6.60μ , 11.47μ , and 13.9μ ; whilst C. Schaefer and M. Schubert observed maxima at 6.77μ , 11.53μ , and 13.54μ with ordinary light, and maxima with ω -light were observed at 6.77μ and 13.54μ , and with ϵ -light, a maximum at 11.53μ . Observations were also made by C. Schaefer and co-workers, W. W. Coblenz, W. Schmidt, and T. Liebisch and H. Rubens. The **absorption spectrum** of ultra-red light was measured by W. W. Coblenz between 1.5μ and 6μ ; and C. Schaefer and co-workers observed the results summarized in Fig. 680, for a plate cut perpendicular to the c -axis. The absorption with wavelength below 9μ is ascribed to the presence of the CO_3 -radicle being characteristic of the carbonates of calcium, barium, magnesium, and lead. Observations were made by E. K. Plyler.

FIG. 680.—The Transmission of the Ultra-red Rays of Siderite.

E. Engelhardt observed that in ultra-violet light, some samples of siderite show a feeble, white **luminescence**, but not **phosphorescence**. C. Doelter observed that **radium radiations** deepen the colour of yellow siderite to brownish-yellow, and a similar change of colour occurs on exposing the crystals to air, and it is due to oxidation, so that radium rays accelerate the speed of aerial oxidation. E. Baur found that the **photochemical transformation** of ferrous carbonate to oxalate: $2\text{FeCO}_3 = (\text{FeO})_2\text{C}_2\text{O}_4$, proceeds neither with nor without sensitizers.

G. Meslin found that a suspension of siderite in carbon disulphide exhibits **magnetic dichroism**—*vide supra*, ferric oxide. L. Graetz found that the **electrical dispersion** of siderite is positive. H. Knoblauch observed the **dielectric polarization** of crystals of siderite. T. Liebisch and H. Rubens found that the **dielectric constant** of siderite is 7.8 for the ordinary ray, and 6.0 for the extraordinary ray; whilst W. Schmidt found for the extraordinary ray 6.85 parallel to the c -axis, and 7.85 normal to the c -axis. W. A. D. Rudge observed the positive **electrification** of siderite when the dust is blown through a wire gauze. A. Abt gave 7154 ohms for the **electrical resistance** of a cm. cube of siderite. J. Königsberger discussed the **electrical conductivity** of ferrous carbonate. T. Liebisch calculated from J. Tyndall's observations that the ratio of the attractive force of two spheres of siderite between the poles of an electromagnet in directions parallel and vertical to the isotropic axes is as 100 : 71. T. W. Case observed no change in the resistance on exposure to light.

M. Faraday showed that siderite is paramagnetic, and he examined the effect with heated crystals. G. Foëx found the sp. **magnetic susceptibility** of siderite parallel and vertical to the chief optical axis to be :

	-186°	-73°	19.5°	42.8°	62.1°	77.7°	102.5°	128.5°
χ { Parallel.	581.16	231.3	142.6	129.8	120.9	111.9	105.3	97.0
Vertical.	180.3	111.4	84.2	79.4	76.0	72.4	69.4	66.0

Above -73° , the sp. susceptibility is a linear function of the temp., and the lines for χ taken parallel and perpendicular to the chief axis are parallel. F. Stutzer and co-workers gave 332×10^{-6} for the coeff. of magnetization; and W. R. Crane,

1.86×10^{-6} for the magnetic susceptibility. The subject was studied by G. Dupouy, L. Pauling and M. L. Huggins, and K. S. Krishnan and co-workers; and the paramagnetic rotation by J. Becquerel and co-workers. H. A. J. Wilkens and H. B. C. Nitze placed siderite amongst the minerals susceptible to attraction in magnetic separations, as in the separation of siderite from zinc blende discussed by E. Clark, G. Prus, M. Bellom, and G. Gromier.

The chemical properties of ferrous carbonate.—Y. A. Ravich-Scherbo, and H. Schneiderhöhn studied the weathering of siderite under the influence of microorganisms. When siderite is heated to redness in **hydrogen**, H. Fleissner and F. Duftschmidt found that carbon dioxide and monoxide and water are evolved, and the residue contains some metallic iron. A current of hydrogen accelerates the thermal decomposition of siderite by carrying the carbon dioxide away from the seat of the reaction. Siderite becomes brownish-red or brownish-black on exposure to **air**, owing to the oxidation of the iron as it passes to limonite; and by a subsequent loss of water it may pass to hæmatite or magnetite. The deoxidation in the latter case may be assisted by the presence of organic matter. In illustration of some of the changes which siderite may undergo in nature, J. R. Blum, M. von Sillem, A. Breithaupt, and R. Nositz mentioned that pseudomorphs of hæmatite after siderite may occur; A. Breithaupt, J. R. Blum, and C. O. Trechmann, of goethite; M. von Sillem, J. R. Blum, E. Weinschenk, G. Grattarola, H. Höfer, J. Samoiloff, A. Schmidt, and E. F. Glockner, of limonite; J. R. Blum, of magnetite; and J. R. Blum, and A. Breithaupt, of chlorite. H. de Sénarmont observed that dry, white ferrous carbonate does not change in dry air, but it slowly coloured in moist air; and S. de Luca found that white and dry ferrous carbonate can be preserved indefinitely in sealed tubes, but with the entry of air and moisture, it is slowly converted into hydrated ferric oxide. A. Krause also noted that precipitated ferrous carbonate, neutral to litmus, is slowly oxidized in air to hydrated ferric oxide almost free from carbon dioxide. G. T. Moody made an analogous observation. The subject was studied by J. Klärning, and F. Duftschmidt. For the decomposition of ferrous carbonate when heated in air, *vide supra*. According to C. Klauer, the moist carbonate becomes dry after exposure to the air for a few days, and is converted into ferric oxide; the oxidation of the partially-dried powder in air may proceed so quickly that the powder becomes hot, and gives off steam. If the moist powder be mixed with sugar, it acquires a coating of syrup which renders it more permanent. R. Phillips also noted how the presence of sugar retards the oxidation of the carbonate, even when it is held in soln. by water impregnated with carbon dioxide. A. Bickel and C. van Eweyk studied the subject. According to G. Just, in the oxidation of ferrous carbonate in soln. in carbonated water: $4\text{Fe}(\text{HCO}_3)_2 + 2\text{H}_2\text{O} + \text{O}_2 = 4\text{Fe}(\text{OH})_3 + 8\text{CO}_2$, the reaction is bimolecular, but the oxygen in the first stage of the process acts molecularly: $\text{Fe}(\text{HCO}_3)_2 = \text{Fe}(\text{OH})_2 + 2\text{CO}_2$, and there may be produced an intermediate "moloxide":

Freshly-precipitated ferrous carbonate takes up oxygen from the air, which thereby becomes activated so that, as shown by O. Baudisch and his fellow-workers, many organic substances—*e.g.*, lactic acid, sugar, and pyrimidine—are simultaneously oxidized. If the ferrous carbonate be not freshly precipitated, it will be oxidized by air, but the oxygen is not activated, and pyrimidine, for instance, is not oxidized. The facility of activating the oxygen may last for a few seconds or minutes.

According to A. Knop, powdered siderite is decomposed by **water** vapour at about 100° forming carbon dioxide, and with coarse-grained siderite, a little carbon monoxide is formed as well; at a red-heat, carbon dioxide and hydrogen are formed with little or no carbon dioxide. A. Gautier observed that when steam acts on siderite at a red-heat, ferric and ferrosic oxides, hydrogen and carbon dioxide are produced. W. Traube and co-workers showed that freshly-precipitated

ferrous carbonate is oxidized by boiling water in the presence of palladium chloride forming hydrogen and carbon dioxide. C. von Hauer said that if carbon dioxide at ordinary press. be passed through water in which iron is suspended, a soln. containing 9.1 parts of FeCO_3 to 10,000 parts of water is obtained; R. Wagner, that 100 parts of water sat. with carbon dioxide can dissolve 0.72 part of FeCO_3 , that one part of FeCO_3 dissolves in 1381 parts of water sat. with carbon dioxide under a press. of 4 to 6 atm.; H. Ehlert and W. Hempel, that a litre of water sat. with carbon dioxide dissolves 6.1907 grms. of freshly-precipitated carbonate under a press. of 2 atm. at 14° ; O. Haehnel, that 100 grms. of a sat. soln. of ferrous carbonate in water at 18° , and in contact with carbon dioxide at a press. of 1 atm., contain 0.072 gm FeCO_3 , and if the press. be 5 atm., 0.077 gm. FeCO_3 dissolves; J. Günzburg, that a litre of water, through which a current of carbon dioxide is continually passed, dissolves 0.504 gm. of precipitated ferrous carbonate at room temp.; A. Cossa, that 10,000 parts of water charged with carbon dioxide at atm. press., dissolve 7.2 parts of siderite at 18° ; J. Ville, that a litre of water charged with carbon dioxide at atm. press., dissolves:

	15°	19°	20°	24°
FeCO_3	1.390	1.185	1.142	1.098 grms.

and L. F. Caro, that 10,000 parts of water sat. with carbon dioxide at a press. p atm., dissolve:

p	1	2	3	4	5	6	7	8 atm.
FeCO_3 { at 5°	3.45	4.21	4.56	5.36	5.74	6.51	6.51	5.51
{ at 20°	3.25	3.73	4.12	4.59	5.07	5.36	5.84	6.12

J. R. Baylis found that the solubility of precipitated ferrous carbonate, S parts Fe per million, in water containing CO_2 parts per million, with the H^+ -ion conc. p_{H} is:

CO_2	8.8	5.0	0	0	0	0
p_{H}	7.2	7.3	8.4	8.6	9.1	9.6
S	4.0	1.0	0.10	trace	0.10	trace

The subject has been discussed in connection with the corrosion of iron (*q.v.*) by H. Henecka, M. Rohland, J. Günzburg, etc. J. Tillmans and B. Klarmann, for instance, say that water with over 100 mgrms. per litre of combined carbonic acid will dissolve iron pipes, whilst water with a H^+ -ion conc. of 0.3×10^{-7} to 4.0×10^{-7} may be considered safe. J. W. Gruner observed that the solubility of siderite in peat-water can be detected after 77 days' exposure, and after 182 days' exposure, the water contains 48 parts of iron per million parts of water. According to J. R. Baylis, the solubility of ferrous carbonate, S parts Fe per million, in water containing CO_2 parts per million, in the H^+ -ion conc. p_{H} is:

CO_2	0	0	2.0	13.2	24.0	33.4
p_{H}	9.6	8.0	7.3	7.0	6.7	6.8—
S	trace	trace	0.8	6.5	12.0	14.0

It is assumed that normal ferrous carbonate is insoluble in water, but it dissolves if carbonic acid be present. It is assumed that in the presence of carbonic acid, the carbonate is in soln. as ferrous hydrocarbonate, $\text{Fe}(\text{HCO}_3)_2$, but that this compound is so unstable that it is known only in aq. soln. The relations between the ferrous carbonate and carbonated water are similar to those which obtain with the alkali and calcium carbonates. The conditions of equilibrium are represented by the five equations: (i), $[\text{H}^+][\text{HCO}_3'] = K_1[\text{H}_2\text{CO}_3]$; (ii), $[\text{H}^+][\text{CO}_3''] = K_2[\text{HCO}_3']$; (iii), $[\text{Fe}^{++}][\text{CO}_3''] = K_3$, the **solubility product**; (iv), $[\text{HCO}_3'] = 2[\text{Fe}^{++}]$; and (v), $\alpha[\text{Fe}(\text{HCO}_3)_2] = [\text{Fe}^{++}]$, where α represents the degree of ionization of ferrous hydrocarbonate. By extrapolation from J. Kendall's values for K_1 , it follows that $K_1 = 3.7 \times 10^{-7}$ at 30° ; C. A. Seyler and P. V. Lloyd's value for $K_2 = 4.91 \times 10^{-11}$ at 25° . The following is a selection from H. J. Smith's solubility data for ferrous hydrocarbonate in water at 30° :

[H ₂ CO ₃]	0.1868	0.2168	0.3116	0.4046	0.6600	0.7154	0.7600
[Fe(HCO ₃) ₂]	0.00245	0.00262	0.00304	0.00332	0.00402	0.00418	0.00434
<i>a</i>	0.912	0.908	0.902	0.896	0.884	0.880	0.878
<i>K</i> × 10 ³	3.91	3.96	4.04	4.02	4.08	4.11	4.18

The average of the whole series of determinations was $K=4.04 \times 10^{-3}$. It is therefore possible to calculate the value of $K_3=[Fe''] [CO_3'']$, since $K_3=4K_2K^3/K_1$; and this gives $K_3=34.53 \times 10^{-12}$. Consequently, if ferrous carbonate were not hydrolytically dissociated, its solubility in pure water free from carbon dioxide would be 5.8×10^{-6} mol. J. Tillmans and B. Klarmann calculated 2.7×10^{-10} , for the solubility product. L. A. Klyachareff studied the effect of ferric hydroxide on the solubility of carbon dioxide in water. W. Feitknecht found the space-lattice of **ferrous oxycarbonate**, $FeCO_3 \cdot 3Fe(OH)_2$, corresponds with alternate layers of hydroxide and normal salt.

J. W. Döbereiner showed that when ferrous carbonate is heated with **potassium hydroxide**, ferrosic oxide is formed and carbon monoxide is given off and potassium carbonate is formed. J. Lemberg said that boiling potash-lye blackens siderite but not so with calspar or dolomite; and R. Böttger found that with precipitated ferrous carbonate, a boiling soln. of potassium hydroxide forms ferrosic oxide. J. R. Baylis found that the solubility of precipitated ferrous carbonate, *S* parts of Fe per million, in water containing CO₂ parts per million in water sat. with **calcium hydroxide**, and with the H⁺-ion conc. p_H is:

CO ₂	9.7	7.9	5.3	8.8	0	0	0
p_H	7.0	7.3	7.5	7.4	8.6	8.6	8.6
<i>S</i>	4.0	2.0	0.8	2.5	trace	trace	0.10

E. Braun observed that ferrous carbonate is readily soluble in a soln. of **ammonium hydrocarbonate**, and rather less in soln. of **sodium and potassium hydrocarbonates**. H. Chandra found that a soln. of 120 grms. NaHCO₃ per litre can dissolve 0.828 grms. of Fe; a sat. soln. of potassium hydrocarbonate 0.908 gm. per litre. If the soln. in ammonium hydrocarbonate or in **rubidium hydrocarbonate** is oxidized in air, complex ferrosic salts are formed, $[Fe_2''Fe(CO_3O)]'$. O. Hauser obtained a colourless soln. of ferrous carbonate in one of **ammonium carbonate**. J. Ville found that the alkali or alkaline **earth carbonates** precipitate hydrated ferrous oxide from carbonated water holding ferrous carbonate in soln., and they are themselves converted into hydrocarbonates; hence the alkali and alkaline earth carbonates have no action on chalybeate water. J. R. Baylis found that with **calcium carbonate** and soln. containing CO₂ parts per million, the solubility of ferrous carbonate, *S* parts Fe per million, when the H⁺-ion conc. of the soln. is p_H is:

Time	2	4	6	29	26 days
CO ₂	3.5	2.6	1.8	5.3	6.6
p_H	7.3	7.4	7.4	7.3—	7.4—
<i>S</i>	1.6	1.3	0.8	1.8	0.6

H. Ehlert obtained the following results for the solubility of ferrous carbonate in water alone, and in water with carbon dioxide at 2 atm. press., containing *S* grms. of ferrous carbonate per litre, and also containing different proportions of the salts—**sodium and magnesium chlorides**, and of **sodium and magnesium sulphates**—indicated in square brackets expressed in terms of grams of salt per 1000 grms. of water, when *S* for water alone is 6.1907. The results with an asterisk refer to water free from carbon dioxide.

[NaCl]	351.2*	50	106.9	175.6	263.4	351.2

F. Wöhler found that when siderite is heated in a current of **chlorine**, it yields a sublimate of ferric chloride and a residue of ferric oxide mixed with some ferrous chloride if the supply of chlorine is deficient: $6\text{FeCO}_3 + 3\text{Cl}_2 = 2\text{FeCl}_3 + 2\text{Fe}_2\text{O}_3 + 6\text{CO}_2$. W. Kangro and R. Flügge added that at 900° , 84.3 per cent. of iron was removed by chlorine from siderite in 120 mins. H. de Sénarmont said that crystalline ferrous carbonate, prepared at a high temp., is but slowly attacked by **acids**, and J. Durocher found that bubbling with the escape of carbon dioxide occurs only when the mixture is heated, but B. Bruzs observed that the artificial ferrous carbonate readily dissolves in acids. Siderite is slowly attacked by **hydrochloric acid** with the evolution of carbon dioxide.

J. J. Berzelius observed that when **hydrogen sulphide** is passed over ferrous carbonate at 100° , iron disulphide, sulphur dioxide, water, and hydrogen are formed. C. Doelter obtained crystals of pyrite by the action of water sat. with hydrogen sulphide on siderite in a sealed tube at 80° to 90° . W. P. Jorissen and J. Rutten found that the action of hydrogen sulphide on precipitated basic carbonate is more rapid than it is on normal ferrous carbonate. H. Lotz investigated the action of air with 19 per cent. of carbon dioxide and 1 per cent. of **sulphur dioxide** on moist siderite, and found that some iron and manganese oxides become soluble in water. A. Gorgeu found that molten **alkali sulphate** mixed with a little **alkali sulphite** reacts with siderite forming crystals of ferrosic oxide with inclusions of manganese, calcium, and magnesium ferrites. J. W. Döbereiner found that at a high temp. conc. **sulphuric acid** acts on powdered siderite forming carbon dioxide, then sulphur dioxide and ferrosic sulphate. According to V. Lenher and C. H. Kao, siderite does not react with **selenium dichloride**.

According to R. H. Brett, ferrous carbonate is insoluble in an aq. soln. of **ammonium chloride or nitrate**, but A. Terreil showed that it is soluble in a boiling soln. of an ammonium salt. G. Linck added that siderite is rapidly oxidized by a mixture of ammonium nitrate and sodium chloride at 60° to 70° . L. Cambi and co-workers found that **nitric oxide** gives with ferrous carbonate an unstable product which could not be isolated; and as the nitric oxide is reduced to nitrous oxide, some hyponitrite is formed. W. Dominik represented the action of **nitric acid** on a mush of ferrous carbonate by: $3\text{FeCO}_3 + \text{HNO}_3 + 4\text{H}_2\text{O} = 3\text{Fe}(\text{OH})_3 + \text{NO} + 3\text{CO}_2$. O. Baudisch and co-workers found that freshly-precipitated ferrous carbonate reduces **alkali nitrites and nitrates** to form ammonia.

H. C. Bolton observed that siderite is not attacked by a cold, sat. soln. of **oxalic acid**; likewise with cold, sat. soln. of **citric, tartaric, or acetic acid**, but if the soln. are hot, the carbonate is attacked. If moist precipitated ferrous carbonate be warmed with **sugar**, C. Klauer found that carbon dioxide is developed, and the ferrous oxide which is formed is protected from oxidation to some extent by the sugar. The reaction was studied by A. Buchner, R. Phillips, etc.—*vide supra*. W. Spiepermann found that the reaction with **alkali thiocyanate**, $\text{KCyS} + \text{FeCO}_3 = \text{KCyO} + \text{FeS} + \text{CO}_2$, begins at 280° , and proceeds rapidly between 280° and 340° . A. Simon and T. Rectz studied the reaction with **benzidine chloride**. I. I. Wanin and A. A. Tschernojarowa found that at 55° to 60° , **benzylidene chloride** reacts turbulently with ferrous carbonate. W. H. Coghill and J. B. Clemmer discussed the **soap** flotation of siderite. H. le Chatelier represented the reaction with **silica** by: $\text{FeCO}_3 + \text{SiO}_2 = \text{FeSiO}_3 + \text{CO}_2 - 7.6 \text{ Cals.}$

H. Rose observed that **ferric oxide** can drive the carbon dioxide from ferrous carbonate. A soln. of a **cuprous salt** in ammonium carbonate was found by E. Braun to be reduced by freshly-precipitated ferrous carbonate to form copper; T. S. Hunt made a similar observation with respect to **cupric chloride**; and H. C. Biddle observed that a precipitated mixture of cupric and ferrous carbonates forms copper and basic ferric carbonate. A. F. Rogers found that siderite reduces a soln. of **silver sulphate** to form silver. J. Ville found that ferrous carbonate is soluble in a soln. of a **ferric salt** with the evolution of carbon dioxide, and the precipitation of hydrated ferric oxide. A. Sismonda investigated the conversion of

siderite into limonite through the action of a soln. of **ferrous sulphate** formed by the weathering of pyrites.

The fact that ferrous carbonate is very sparingly soluble in water alone, but is soluble in water containing carbon dioxide in soln., is explained by analogy with the behaviour of calcium carbonate, by assuming that soluble **ferrous hydrocarbonate**, $\text{Fe}(\text{HCO}_3)_2$, is formed, although this salt has not yet been prepared in the solid state. O. Haehnel assumed that this salt will appear as a solid phase in soln. with carbon dioxide under a press. exceeding 40 atm.; and H. J. Smith calculated that the press. of carbon dioxide with solid ferrous hydrocarbonate at 25° is greater than 25 atm.

L. Gmelin stated that iron dissolves in an aq. soln. of carbon dioxide with the evolution of hydrogen. H. Klut also observed the evolution of hydrogen when water free from dissolved oxygen acts on iron. G. T. Moody showed that when iron is left for 26 days in contact with a soln. of carbon dioxide at atm. press., 1.66 grms. of iron per litre dissolve as ferrous hydrocarbonate; and J. Günzburg found that in the absence of oxygen, water sat. with carbon dioxide under atm. press. dissolves about a gram of iron per litre in a few days. The soln. of hydrocarbonate is stable if it be separated from the excess of iron, but if it be shaken with iron, with or without the introduction of more carbon dioxide, white ferrous carbonate is formed. E. Müller and H. Henecka found that with the carbon dioxide under a press. of 50 atm., water with pulverulent iron in suspension at 30° to 100° attains a maximum concentration of hydrocarbonate, and this the more rapidly the higher the temp. The concentration of the hydrocarbonate in soln. then decreases owing to its decomposition into ferrous carbonate, etc. At 20° , a concentration of 2.249 grms. of iron per litre is attained, but, as shown in Fig. 681, the maximum is less pronounced at 20° to 60° than it is at 80° to 100° . The decrease in the concentration of the hydrocarbonate after attaining a maximum was also observed by N. N. Gavriloff and co-workers. The observations of J. Kendall, C. A. Seyler and P. V. Lloyd, H. J. Smith, and J. Tillmans and B. Klarmann have just been discussed.

M. Golfier-Besseyre prepared a soln. of the hydrocarbonate by passing carbon dioxide into a flask filled with water and iron turnings, and M. Sarzeau said that the reaction is accelerated if pieces of platinum wire are also present. The formation of a soln. of hydrocarbonate by the action of a soln. of carbonic acid on iron was observed by A. C. Brown, H. Bunte and A. Schmidt, F. C. Calvert, W. R. Dunstan and co-workers, J. Günzburg, C. von Hauer, B. Klarmann, W. Leybold, A. Simon and K. Kötschau, L. N. Vauquelin, and J. Ville. According to G. Stadnikoff and N. Gavriloff, the dissolution of iron is faster if the carbon dioxide be passed through the water in the presence of iron than if the water be first sat. with carbon dioxide; and the rate of dissolution increases the faster the current of gas. Rusty iron dissolves more quickly than clear iron; iron etched with hydrochloric acid dissolves more rapidly than the untreated iron; iron previously used for the preparation of the hydrocarbonate dissolves less quickly than ordinary iron. If air be present so that the ratio $\text{CO}_2 : \text{Air} = 1 : 1$, the rate of dissolution of iron is independent of time; if the ratio is $1 : 3$, the rate of dissolution is still independent of time, but it is less than when the ratio is $1 : 1$, since part of the iron goes into oxide. N. N. Gavriloff and co-workers found that if over 5 per cent. of oxygen and 14 to 15 per cent. of carbon dioxide are present in flue-gases, the velocity of formation of the hydrocarbonate is retarded owing to the formation

FIG. 681.—Solubility of Iron in Water Carbonated at 50 atm. Pressure.

of a layer of oxide on the metal. A. Simon and K. Kötschau found that by triturating ferrum reductum in a porcelain mortar, in the presence of carbon dioxide and moisture, some ferrous hydrocarbonate is formed. F. Haber and F. Goldschmidt said that some hydrocarbonate is formed with iron as anode in an aq. soln. of carbon dioxide with a current of 0.005 amp. per sq. cm.

L. Gmelin, A. Buchner, and G. Just obtained a soln. of the hydrocarbonate by the action of carbonated water on precipitated ferrous carbonate. C. Peeters said that the hydrocarbonate is precipitated by mixing aq. soln. sat. with carbon dioxide containing respectively a ferrous salt and an equimolar proportion of an alkali hydrocarbonate together with 1 to 5 per cent. of an alkali tartrate, citrate, lactate, etc. W. Leybold found that precipitated ferrous hydroxide dissolves in carbonated water more slowly than iron. N. N. Gavriloff and S. K. and P. K. Mel discussed the formation of the hydrocarbonate from carbon dioxide and iron oxide. F. K. Cameron and W. O. Robinson measured the vap. press., p cm., of carbon dioxide over moist hydrated ferrous oxide (0.1231 grm. FeO), and found, for added carbon dioxide :

$[\text{CO}_2]$.	0.0	0.014	0.070	0.098	0.126	0.182	0.224	0.252 grm.
p	76	76	76	102	134	199	245	274 cm.

The break in the curve, Fig. 682, represents the point where all the ferrous oxide has been converted into normal carbonate. The result is taken to show that with vap. press. less than 4.5 atm. of carbon dioxide, no other than the normal carbonate, or a hydrate of the normal carbonate, can exist as a solid phase. W. Thörner said that some hydrocarbonate is formed when carbonated water acts on pyrite: $\text{FeS}_2 + 2\text{CO}_2 + 2\text{H}_2\text{O} = \text{Fe}(\text{HCO}_3)_2 + \text{S} + \text{H}_2\text{S}$.

FIG. 682.—The Adsorption of Carbon Dioxide by Hydrated Ferrous Oxide.

H. Molisch observed that light does not accelerate the oxidation of ferrous hydrocarbonate to ferric hydroxide; and in the absence of air, A. Simon and K. Kötschau found that the soln. is not decomposed by ultra-violet light; E. C. C. Baly observed the formation of carbohydrates when a soln. of the hydrocarbonate is exposed to ultra-violet light.

O. Baudisch and D. Davidson found that when the soln. is exposed to the light of a carbon arc, hydrogen is evolved, and the ferrous hydrocarbonate is oxidized. O. Haehnel found the electrical conductivity of aq. soln. at 18° to be :

FeCO_3	0.077	0.072	0.01	0.005 per cent.
$\text{Mho} \times 10^{-6}$	369	349	195	96

Measurements were also made by J. Günzburg, who found that the transport number of the Fe^{++} -ion is independent of the age of the soln., and amounts to about 0.5. The colourless soln. of ferrous hydrocarbonate—called *steel-water*, or *chalybeate water*—has a slightly ferruginous taste, and L. Gmelin observed that when the soln. is exposed to air, hydrated ferric oxide is precipitated and carbon dioxide is evolved. If the excess of carbon dioxide is expelled from the soln. without the entry of air, M. Golfer-Besseyre found that white ferrous carbonate is precipitated; and A. C. Brown, that in an atm. free from oxygen and carbon dioxide, gas is evolved and ferrous carbonate is precipitated, but in the presence of oxygen, some ferric hydroxide is formed. If the aq. soln. be boiled in a flask with a reflux condenser, all the carbon dioxide is expelled, and, according to W. R. Whitney, colloidal ferric oxide is formed. In the absence of air, the soln. remains clear and colourless, but G. T. Moody found that when the soln. is boiled, green ferrous carbonate is precipitated, and it becomes reddish-brown in air; atm. oxygen decomposes the soln. precipitating ferrous and ferric hydroxides, and ferrous carbonate.

J. Ville noted that the presence of chlorides and sulphates retard the decomposition of chalybeate water by aerial oxidation; and the presence of sugar, or glycerol, was found by C. Klauer, G. Bischof, R. Phillips, etc.—*vide supra*—to make the soln. a little more stable in air. L. N. Vauquelin observed that with hydrogen sulphide, the soln. does not give a precipitate of black iron sulphide until the liquid has been exposed to the air for some time; the sulphide is formed as the carbon dioxide escapes. C. H. Pfaff added that whilst tincture of galls gives no coloration or precipitate with ferrous salts in the absence of all traces of ferric salts, a purple coloration or precipitate is produced with a soln. of ferrous hydrocarbonate. L. Cambi and A. Clerici found that nitric oxide forms an unstable product when it acts on a soln. of ferrous hydrocarbonate.

Complex ferrous carbonates.—O. Hauser also obtained a colourless soln. of ferrous carbonate in one of ammonium carbonate; presumably **ammonium ferrous carbonate** is formed. According to W. C. Reynolds, **potassium ferrous carbonate**, $K_2CO_3 \cdot FeCO_3 \cdot 4H_2O$, is produced by mixing, out of contact with air, a conc. soln. of ferrous chloride mixed with an excess of potassium carbonate. The white precipitate first formed soon dissolves producing a greenish soln. which deposits white, scaly crystals of the double salt.

A. Breithaupt described a mineral from Traversella, Piedmont, which he called *Mesitenspath* or *mesitine*, and this was later modified to **mesitite**—from *μεσίτης*, a go-between—in allusion to its being intermediate between magnesite and siderite. The analysis approximates magnesium ferrous tricarbonates, $2MgCO_3 \cdot FeCO_3$. He afterwards obtained a similar mineral from the same locality, and from Thurnberg, Saxony, and he called it **pistomesite**—from *πιστός*, reliable, and *μεσίτης*, a go-between—because pistomesite is nearer the middle between siderite and magnesite than mesitite, being **magnesium ferrous carbonate**, $MgCO_3 \cdot FeCO_3$. Analyses were reported by O. W. Gibbs, J. Fritsche, A. Patera, and C. Ettling. Probably both are stages in a series of solid soln.—*vide supra*. The colour of the minerals is yellowish-white, yellowish-grey, or yellowish-brown; and the crystals are rhombohedral. The $(10\bar{1}1)$ -cleavage is perfect. The sp. gr. of mesitite is 3.35 to 3.36, and of pistomesite, 3.42. The hardness is 3.5 to 4.0. There are also F. Sandberger's **ferrobrucite**, $(Mg, Fe)O \cdot CO_2 \cdot 10H_2O$, discussed by P. Gaubert; **breunerite** is $3FeCO_3 \cdot 8MgCO_3$ approximately; V. Zsivny's $(Fe, Mg, Ca)CO_3$, where $Fe : Mg : Ca = 1 : 49 : 50$ —*vide ankerite*, 4. 29, 367; and E. Artini's pink, micaceous mineral, **brugnatellite**, found in the Val Malenco, Lombardy, and also on the Monte Ramazzo, Luguria, which approximates $MgCO_3 \cdot 5Mg(OH)_2 \cdot Fe(OH)_3 \cdot 4H_2O$. It is uniaxial with a perfect cleavage, and a refractive index of 1.533 with Na-light; the optical character is negative. It is pleochroic being ω =yellowish-red, and ϵ =colourless. R. L. Codazzi found an ash-brown complex carbonate, $(Ca, Mg, Fe, Ce)CO_3$, in Muzo, Coscuez, and Coper, Colombia, and named it **codazzite**—after A. Codazzi. It belongs to the rhombohedral system; its sp. gr. is 2.5, and its hardness, 4.

Solid soln. of manganous and ferrous carbonates occur in nature as **rhodochrosite-siderite**, or **manganosiderite** reported by A. Breithaupt, who called the mineral **oligonite**. It was called *manganosphärte* by K. Busz, but E. B. Mayo and W. J. O'Leary, W. E. Ford, E. H. Kraus and W. F. Hunt, S. Koch and L. Zombory, and N. H. and A. N. Winchell preferred oligonite. The optical properties were studied by N. Sundius, E. T. Wherry and E. S. Larsen, G. F. Loughlin, W. E. Ford, and E. B. Mayo and W. J. O'Leary.

Ferric carbonates.—According to L. Gmelin, the precipitate obtained by adding potassium carbonate to a soln. of ferric nitrate, when thoroughly washed, is hydrated ferric oxide free from carbon dioxide; and E. Soubeiran found that the precipitate obtained from ferrous salts under like conditions, when exposed in a thin layer to moist air in a cellar for six months, contains about 8.3 per cent. of carbon dioxide, 20 per cent. of water, and 71.4 per cent. of ferric oxide—no ferrous iron was present. W. Scheermesser, R. Rother, K. Seubert and M. Elten, A. Langlois,

J. Lefort, W. Wallace, J. Barratt, and T. Parkman obtained similar results by precipitating soln. of ferric salts with alkali or ammonium carbonates. The ratios $\text{Fe}_2\text{O}_3 : \text{CO}_2 : \text{H}_2\text{O}$ ranged from 9 : 1 : 12 to mixtures with only 1.36 per cent. carbon dioxide. K. Feist triturated crystals of ferric chloride with a slight excess of hydrated sodium carbonate, and when carbon dioxide was no longer evolved, the liquid mixture was treated with water and the precipitate allowed to settle. When dried, a precipitate 7 : 1 : 8 was obtained. The composition varied with the time of washing, showing that the treatment with water induced hydrolysis.

Taking the mol. ratios $\text{Fe}_2\text{O}_3 : \text{CO}_2 : \text{H}_2\text{O}$, the following basic salts have been reported : 3 : 1 : 6 and 9 : 1 : 12, by W. Wallace ; 3 : 1 : 8, by J. Barratt ; 3 : 1 : 4, by W. Wallace, and J. Barratt ; 1 : 1 : n , by T. Parkman ; 6 : 3 : 12, by R. Rother ; and 10 : 1 : 28, by K. Seubert and M. Elten.

All this shows that if **ferric carbonate**, $\text{Fe}_2(\text{CO}_3)_3$, is formed, it is immediately hydrolyzed in aq. soln. P. N. Raikow observed that carbon dioxide acting on freshly-precipitated ferric oxide forms no ferric carbonate. J. Tillmans and co-workers found that precipitated hydrated ferric oxide adsorbs carbon dioxide from the soln., and the results with a fresh preparation did not differ from those with one 8 days old ; a precipitate obtained from a hot soln. adsorbed less than one from a cold soln. When the amount of precipitant, sodium hydrocarbonate, is constant, the amount of adsorbed carbon dioxide increases with the conc. of that gas in the soln. ; and when the amount of carbon dioxide is kept constant, the amount of carbon dioxide adsorbed increases with the conc. of sodium hydrocarbonate. It is assumed that the adsorption is attended by the formation of **ferric hydroxycarbonate**, $\text{Fe}(\text{OH})\text{CO}_3 \cdot n\text{Fe}(\text{OH})_3$. F. K. Cameron and W. O. Robinson found the vap. press., p cm., of carbon dioxide over wet ferric hydroxide at 0° in the presence of the number of grams of carbon dioxide indicated by the square brackets :

$[\text{CO}_2]$. . .	0	0.014	0.070	0.140	0.182	0.224	0.256 grm.
p . . .	76	85	148	224	273	318	368 cms.

The whole of the results fall on a straight line, and show practically no adsorption, and this is in agreement with the observations of P. N. Raikow. A. Gatterer observed that the hydrosol of ferric hydroxide absorbs 20 per cent. more carbon dioxide than does the carbonate alone ; consequently, he inferred that a complex ferric carbonate is formed. The subject was studied by A. von Dobeneck, and E. Reichardt and E. Blumtritt—*vide* hydrated ferric oxide.

According to O. Hauser, the precipitates formed by adding ammonium carbonate to soln. of ferrous or of ferric salts are soluble in an excess of the precipitant. The ferric salt furnishes a blood-red liquid from which the iron is precipitated by hydrogen sulphide, by reagents which react with carbonates, or by boiling alkali-lye, but not by potassium ferrocyanide ; whereas prussian blue dissolves in an aq. soln. of ammonium carbonate to form a violet-red soln. It is therefore assumed that the liquid contains **ammonium ferric carbonate**, and it can be preserved in a closed vessel for several weeks, but deposits hydrated ferric oxide on evaporation.

J. Lefort could not prepare a definite **ferrosic carbonate**, although the partially-oxidized precipitate formed when an alkali carbonate is added to a soln. of a ferrous salt, may contain both ferrous and ferric carbonates or oxycarbonates. The white precipitate obtained with ferrous salts is less readily dissolved by an excess of ammonium carbonate, and the colourless soln., on treatment with hydrogen dioxide, or on exposure to air, rapidly turns brown ; but when oxidized by a limited quantity of air, it deposits **ammonium ferrous ferric oxycarbonate**, $\text{NH}_4\text{CO}_3 \cdot \text{FeCO}_3 \cdot \text{FeCO}_3 \cdot \text{FeO} \cdot 2\text{H}_2\text{O}$, in the form of stellate aggregates of small, doubly-refracting, green prisms. When the crystals are exposed to air, they become olive-green, and finally brown, owing to the formation of hydrated ferric oxide. The salt dissolves in dil. acids, with evolution of carbon dioxide, to form a yellowish-green soln., and when treated with alkali hydroxides, it yields

ammonia, and black, strongly magnetic, ferrosic oxide. R. Frey and J. Burghelle described a pink, pleochroic, basic carbonate, $2\text{Fe}_2\text{O}_3 \cdot \text{Cr}_2\text{O}_3 \cdot 27\text{MgO} \cdot 0.6\text{CO}_2 \cdot 54\text{H}_2\text{O}$, from Bou Oufroh, in Morocco. The sp. gr. is 2.1 to 2.2; and the hardness, 1.

§ 49. The Iron Nitrates

H. Davy¹ showed that when conc. nitric acid acts upon iron, nitric oxide is given off with great rapidity, and a great rise of temp.; the soln. assumes a yellow tint, and as the process goes on, a yellow oxide is precipitated. The soln. was assumed to contain **ferric nitrate**, $\text{Fe}(\text{NO}_3)_3$, because it gives a red precipitate with alkalies, and a bright blue precipitate with potassium ferrocyanide. On the other hand, with very dil. nitric acid, say of sp. gr. 1.16, the iron dissolves without the assistance of heat, and without the evolution of gas for some time, and the soln. becomes dark olive-brown. The liquid was assumed to contain **ferrous nitrate**, $\text{Fe}(\text{NO}_3)_2$, because it gives a pale green precipitate with alkalies, and a pale green coloration with potassium ferrocyanide. Iron thus forms two nitrates as well as two sulphates, two chlorides, etc. The existence of the green nitrate was not suspected by J. L. Proust. H. Davy said that he had not succeeded in preparing ferrous nitrate which gave only a white precipitate with potassium ferrocyanide, that is, a soln. which contained only iron "at its minimum oxidation"; for when

pure, green iron oxide is dissolved by very dil. nitric acid, a small quantity of the acid is generally decomposed, which is likewise the case when potassium nitrate is decomposed by ferrous sulphate. A soln. is said to be obtained by treating ferrous sulphate with an eq. quantity of barium nitrate, and evaporating the filtrate in vacuo over sulphuric acid.

A. Scheurer-Kestner observed that with nitric acid of sp. gr. 1.034, ferrous and ammonium nitrates are formed; with acid of sp. gr. 1.073, ferrous, ferric, and ammonium nitrates; with acid of sp. gr. 1.115, ferric nitrate alone; and with acid of sp. gr. over 1.115, ferric and basic ferric nitrates are produced. The subject was investigated by W. Heldt. According to J. M. Ordway, the progress of the reaction depends on the temp. as well as on the conc. of the acid, and it is also affected by the nature of the impurities—e.g., sulphur and phosphorus—in iron. With nitric acid of sp. gr. 1.05, iron of a high degree of purity furnishes ferrous nitrate, but more conc. acids, a mixture of ferrous and ferric nitrates is produced. C. Montemartini observed that ferrous nitrate is first formed even with conc. acids, but it is then oxidized to ferric nitrate by the nitrogen oxides simultaneously formed. N. A. E. Millon found that the presence of platinum chloride influences the formation of the ferric salt, and A. Quartaroli made a similar observation with respect to urea. The formation of iron nitrates and nitrites in hydrated ferric oxide, or in iron-rust, which has been exposed to the air for a long time, was discussed by A. Baumann, E. Donath, and H. Ditz and co-workers. F. W. Bergstrom noted that the salt is formed by the action of a soln. of ammonium nitrate in liquid ammonia on iron wire.

The preparation of ferrous nitrate.—J. J. Berzelius said that in preparing a soln. of ferrous nitrate by dissolving iron in nitric acid, the iron should be immersed in water, and nitric acid, free from nitrous acid and chlorine, should be added in small portions, with constant agitation, so that the temp. may not rise above 50°; as often as the liquid cools down, fresh acid should be added. Under these circumstances no gas is evolved, but some ammonium nitrate is formed: $4\text{Fe} + 10\text{HNO}_3 = 4\text{Fe}(\text{NO}_3)_2 + \text{NH}_4\text{NO}_3 + 3\text{H}_2\text{O}$. A. Pleischl found that with a mixture of 1 part of acid with 3 of water, a mixture of nitric and nitrous oxides is at first evolved, and afterwards only nitric oxide. J. J. Berzelius also noted that ferrous sulphide and well-cooled nitric acid forms a soln. of ferrous nitrate and gives off hydrogen sulphide. If the temp. is allowed to rise, some ferric salt is formed. J. M. Ordway also dissolved ferrous sulphide in well-cooled nitric acid of sp. gr. less than 1.12, and evaporated the soln., as nearly as possible, at 60°. C. F. Schönbein regarded the crystals obtained from a soln. of the scale-oxide of iron in conc. nitric acid as ferric nitrate; L. N. Vauquelin, as ferrous nitrate which is converted into ferric nitrate and a yellow deposit on exposure to air. I. Traube, and A. A. Noyes and B. F. Brann obtained an aq. soln. by the action of barium nitrate on a soln. of ferrous sulphate, and filtering off the precipitated barium sulphate; R. Funk said that the soln. so obtained are very dilute, and are particularly prone to oxidation on evaporation, and he recommended triturating solid lead nitrate with an equivalent proportion of hydrated ferrous sulphate along with some dilute alcohol, and afterwards evaporating the soln. E. Weitz and H. Müller recommended triturating the salts first with a little water, adding a few drops of soda-lye to avoid the effect of free acids, adding an equal vol. of alcohol, and evaporating the filtered soln. in air. A. A. Noyes and B. F. Brann reduced a soln. of ferric nitrate with silver: $\text{Fe}(\text{NO}_3)_3 + \text{Ag} \rightleftharpoons \text{AgNO}_3 + \text{Fe}(\text{NO}_3)_2$; and W. H. Ross, and O. Baudisch and E. Mayer found that ferrous nitrate is formed when a soln. of ferric nitrate is exposed to sunlight, or to ultra-violet light; but M. Schneider observed no reduction in sunlight.

Anhydrous ferrous nitrate has not been prepared; when the aq. soln. is evaporated, green, monoclinic prisms of the *hexahydrate*, $\text{Fe}(\text{NO}_3)_2 \cdot 6\text{H}_2\text{O}$, are formed. J. M. Ordway found that 100 parts of water dissolve 200 parts of the crystals at 0°; 245 parts at 15°; and 300 parts at 25°. R. Funk and F. Mylius obtained rather

larger values, and their results, summarized in Fig. 683, are as follow, when the solubility, S , refers to grams of $\text{Fe}(\text{NO}_3)_2$ in grams of soln. :

	-145.5°	-20°	-28°	-27°	-19°	-12°	-10°	0°	20°	60.5°
S	29.8	32.8	35.5	35.6	36.5	39.4	39.6	41.5	45.5	62.5
	Ice		$\text{Fe}(\text{NO}_3)_2 \cdot 9\text{H}_2\text{O}$				$\text{Fe}(\text{NO}_3)_2 \cdot 6\text{H}_2\text{O}$			

While the hexahydrate separates from conc. soln. when the temp. is between -12° and 60.5° , the *enneahydrate*, $\text{Fe}(\text{NO}_3)_2 \cdot 9\text{H}_2\text{O}$, separates when the temp. is between -12° and -28° . A. Gorboff concluded from insufficient evidence that there is an *octodecahydrate*, $\text{Fe}(\text{NO}_3)_2 \cdot 18\text{H}_2\text{O}$, and a *pentadecahydrate*, $\text{Fe}(\text{NO}_3)_2 \cdot 15\text{H}_2\text{O}$. H. C. Jones and H. P. Bassett discussed the relation between the temp. of crystallization, and the number of mols. of water of crystallization of the salt.

The physical properties of ferrous nitrate.—R. Funk said that the hexahydrate furnishes pale green, rhombic plates. J. M. Ordway found that soln. sat. at 0° , 15° , and 25° have respectively the sp. gr. 1.44, 1.48, and 1.50. R. Funk observed that the soln. sat. at 18° has a sp. gr. 1.497; and I. Traube, that soln. with 4.554 and 6.052 per cent. $\text{Fe}(\text{NO}_3)_2$ have the respective sp. gr. 1.03556 and 1.04835. I. Traube discussed the mol. soln. vol.

R. Funk said that the hexahydrate melts at 60.5° . The molten salt was found by R. Funk to decompose with the evolution of a gas if heated a little above the m.p.; a dark red residue remains. According to C. Montemartini and E. Vernazza, the decomposition of ferrous nitrate by heat is represented by: $2\text{Fe}(\text{NO}_3)_2 = 2\text{FeO} + 4\text{NO}_2 + \text{O}_2$; but since the ferrous oxide is oxidized, and the water of crystallization is always present up to 100° , the resultant reaction is symbolized: $3\text{Fe}(\text{NO}_3)_2 + 7\text{H}_2\text{O} \rightarrow 3\text{Fe}(\text{OH})_3 + 5\text{HNO}_3 + \text{NO}$. The ferric oxide is present as $\text{Fe}_2\text{O}_3 \cdot \text{H}_2\text{O}$. The heat of formation was studied by P. A. Favre and J. T. Silbermann; M. Berthelot gave: $(\text{Fe}, \text{N}_{2\text{gas}}, 3\text{O}_{2\text{gas}}, \text{Aq.}) = 119.0$ Cals.; and J. Thomsen, $(\text{Fe}, \text{O}_{\text{gas}}, \text{N}_2\text{O}_{5\text{gas}}, \text{Aq.}) = 89.67$ Cals.; J. Thomsen also gave for the heat of neutralization: $\text{Fe}(\text{OH})_2 + 2\text{HNO}_3 \cdot \text{Aq.} = \text{Fe}(\text{NO}_3)_2 \cdot \text{Aq.} + 21.339$ Cals., and M. Berthelot, 21.5 Cals.

F. Allison and E. J. Murphy studied the magneto-optic properties; H. M. Vernon, the change in the colour of aq. soln. on dilution or on raising the temp.; and S. Jakubsohn and M. Rabinowitsch, the electrical conductivity of the soln. H. Buff observed that in the electrolysis of dil. soln. of ferrous nitrate, iron and hydrated ferric oxide are formed; and J. H. Paterson said that between platinum electrodes, either iron, or with a small concentration and low current density, ferrous hydroxide is deposited. A. Schükareff found that when the electrolysis is conducted between platinum electrodes, in a magnetic field, a magnetochemical effect appears. G. Wiedemann made some observations on the magnetic susceptibility of the soln.

The chemical properties of ferrous nitrate.—J. M. Ordway reported that the crystals of the hexahydrate are stable in the cold, but the crystals, freed from the mother-liquor, rapidly form dark red basic ferric nitrate. R. Funk added that at ordinary temp. the crystals cannot be kept a day or two without browning, but at 0° they are stable. The crystals darken in a few minutes if traces of impurities, like hyponitrous acid, are present. J. J. Berzelius showed that the neutral aq. soln. decomposes when heated forming a basic ferric nitrate. J. M. Ordway added that the neutral soln. of ferrous nitrate, not too concentrated, can be boiled without decomposition, but if free acid is present, nitric oxide is evolved. R. Funk found that it is not possible to evaporate the soln. without some oxidation. W. Feitknecht observed that the space-lattice of **ferrous oxynitrate**, $\text{Fe}(\text{NO}_3)_2$,

FIG. 683.—The Solubility of Ferrous Nitrate.

$4\text{Fe}(\text{OH})_2$, corresponds with alternate layers of the normal salt and of the hydroxide.

J. Thomsen said that the thermal value of the reaction between ferrous nitrate and hydrogen sulphide, all in aq. soln., is -6.77 Cals., and added that the negative value explains how hydrogen sulphide does not precipitate the sulphide from a soln. of ferrous nitrate. F. Haber electrolyzed a soln. of ammonium nitrate, sat. at 0° , between an iron cathode and a carbon anode, in a diaphragm cell, with a current density of 0.02 amp. per sq. dm., and obtained a golden-yellow liquid which, according to A. Kaufmann, contains an ammine of ferrous nitrate. He also said that a similar liquid is produced when powdered iron is digested with a hot, conc., ammoniacal soln. of ammonium nitrate. Observations were also made by W. Vaubel; E. Weitz and H. Müller said that the golden-yellow colour is due to the presence of complex nitrites, and added that **ferrous hexamminonitrate**, $\text{Fe}(\text{NH}_3)_6(\text{NO}_3)_2$, is formed by passing ammonia into a cold soln. of 5 grms. each of hexahydrated ferrous and ammonium nitrates in 20 c.c. of water from which air has been displaced by hydrogen. When the ferrous hydroxide first precipitated has dissolved, the liquid is filtered from the hydrated ferric oxide in an atm. of ammonia, and again treated with ammonia gas until a precipitate is formed. The precipitate is washed with ammoniacal alcohol, and then with dry ether, free from peroxide. The yellow tinge of the green, octahedral crystals is attributed to the presence of some colloidal ferric hydroxide. F. W. Bergstrom noted that the hexammine is formed in liquid ammonia. According to E. Weitz and H. Müller, if the filtered liquid from the hydrated ferric oxide be treated with nitric oxide, a mixture of crystals of the hexammine with black octahedra of **ferrous nitrosyl-pentamminonitrate**, $[\text{Fe}(\text{NO})(\text{NH}_3)_5](\text{NO}_3)_2$, is formed. The salt oxidizes in air with the evolution of ammonia, and it gives off nitric oxide when treated with acids. H. Davy observed that the soln. readily absorbs nitric oxide, and when the sat. soln. is heated, gas is liberated, and hydrated ferric oxide is precipitated. E. Weitz and H. Müller assumed that a **ferrous nitrosylpentaquonitrate**, $[\text{Fe}(\text{NO})(\text{H}_2\text{O})_5](\text{NO}_3)_2$, is formed.

W. Schrenzlowa found that **cuprous and ferrous nitrates** form isodimorphous solid soln. D. Vitali found that silver oxide decomposes the nitrate completely with the separation of ferrous hydroxide. M. V. Dover studied the reaction: $\text{AgNO}_3 + \text{Fe}(\text{NO}_3)_2 \rightleftharpoons \text{Fe}(\text{NO}_3)_3 + \text{Ag}$, and A. A. Noyes and B. F. Brann gave 172.3 Cals. for the thermal value of the reaction in soln. L. Losana observed that finely-divided barium ferrate suspended in water, ferrous ferrate is formed. J. Jettmar discussed the action of the nitrate on animal skins in the tanning industry. E. H. Kraus reported that he prepared **didymium ferrous dodecanitrate**, $2\text{Di}(\text{NO}_3)_3 \cdot 3\text{Fe}(\text{NO}_3)_2 \cdot 24\text{H}_2\text{O}$, but could not repeat the result. The crystals were trigonal with the axial ratio $a:c=1:5590$, and $\alpha=80^\circ 8'$; the (100)-cleavage distinct; the optical character negative; the birefringence strong; and the sp. gr. was 2.257 .

As indicated above, H. Davy² observed that if iron be dissolved in conc. nitric acid, **ferric nitrate**, $\text{Fe}(\text{NO}_3)_3$, is produced. If the acid be in excess, a brown soln. is formed, and if the acid be not in excess, a yellowish-brown basic salt is produced. The observations of A. Scheurer-Kestner, indicated above, showed that with nitric acid of sp. gr. 1.115 , ferric nitrate alone is formed; with a more dilute acid, ferrous nitrate appears, and with a more conc. acid, a basic ferric nitrate is formed. J. M. Ordway's observations are also discussed in connection with ferrous nitrate. W. Heldt proposed the hypothesis that the white skin formed on iron is anhydrous ferric nitrate and that it protects the iron from attack—*vide supra*, passivity—and he further assumed that the anhydrous salt so formed is insoluble in nitric acid of sp. gr. 1.45 to 1.54 . Otherwise, the anhydrous salt has not been isolated.

U. Antony and G. Gigli prepared the salt by adding the calculated quantity of nitric acid to a soln. of the basic nitrate, and this gives a neutral soln., but evaporating the soln. in vacuo over sulphuric acid does not furnish crystals. The

crystallization of the soln. is possible only in the presence of an excess of nitric acid. B. Lambert and J. C. Thomson electrolyzed a soln. of purified ferric chloride between iridium electrodes, and dissolved the electrodeposited iron in purified, dil. nitric acid. The soln. was concentrated on a water-bath, and re-crystallized several times from its soln. in conc. nitric acid. T. W. Richards and co-workers, G. P. Baxter and C. R. Hover, and F. K. Bell and W. A. Patrick described the preparation of the salt of a high degree of purity.

M. Z. Jovitschitsch prepared a soln. by passing nitrogen peroxide through a tower packed with pieces of glass, and finely-divided ferric oxide, and down which water trickled. C. Méne described the technical preparation of the salt by the action of nitric acid on iron slags; and G. Kingsley, by the action of nitric acid on pyrites.

The hydrates of ferric nitrate.—The equilibrium relations of the system $\text{Fe}_2\text{O}_3\text{--N}_2\text{O}_5\text{--H}_2\text{O}$, at 25° , were partially worked out by F. K. Cameron and W. O. Robinson. They observed as solid phases with soln. containing the percentage proportions $\text{Fe}_2\text{O}_3 : \text{N}_2\text{O}_5$: (i) ferric hydrotetranitrate, $\text{Fe}_2\text{O}_3 \cdot 4\text{N}_2\text{O}_5 \cdot 18\text{H}_2\text{O}$, with 3.25 to 3.93 : 49.6 to 47.2; (ii) enneahydrated ferric nitrate, $\text{Fe}_2\text{O}_3 \cdot \text{N}_2\text{O}_5 \cdot 18\text{H}_2\text{O}$, with 4.49 to 15.22 : 55.2 to 30.5—G. Malquori gave 5.99 : 45.84; (iii) G. Malquori gave for the transition point of the enneahydrate to the hexahydrate 9.25 : 46.48; (iv) hexahydrated ferric nitrate, $\text{Fe}_2\text{O}_3 \cdot 3\text{N}_2\text{O}_5 \cdot 12\text{H}_2\text{O}$, 9.28 : 48.88; and (v) F. K. Cameron and W. O. Robinson found the so-called basic ferric nitrates appear with 15.40 to 1.78 : 29.52 to 2.21. The following is a selection from F. K. Cameron and W. O. Robinson's results:

Sp. gr.	1.032	1.127	1.498	1.496	1.404	1.465	1.407	1.419
Fe_2O_3	1.78	5.79	15.40	15.22	5.02	4.49	3.93	3.52
N_2O_5	2.21	9.00	29.52	30.50	47.50	55.2	47.2	49.6
	Solid solution			$\text{Fe}_2\text{O}_3 \cdot 3\text{N}_2\text{O}_5 \cdot 18\text{H}_2\text{O}$			$\text{Fe}_2\text{O}_3 \cdot 4\text{N}_2\text{O}_5 \cdot 18\text{H}_2\text{O}$	

The results are plotted in Fig. 684. No definite basic salts are formed at 25° . The so-called basic salts are solid soln. of the three components, $\text{Fe}_2\text{O}_3 \cdot m\text{N}_2\text{O}_5 \cdot n\text{H}_2\text{O}$,

FIG. 684.—The Ternary System : $\text{Fe}_2\text{O}_3\text{--N}_2\text{O}_5\text{--H}_2\text{O}$, at 25° .

FIG. 685.—The Ternary System : $\text{Fe}(\text{NO}_3)_3\text{--HNO}_3\text{--H}_2\text{O}$, at 25° .

for the lines joining the points representing the composition of the liquid and the corresponding solid phase do not meet at a common point or points. When nitric acid is in excess, the lines do meet at a point corresponding with the enneahydrate. There is also an acidic nitrate, **ferric hydrotetranitrate**, $\text{Fe}(\text{NO}_3)_3 \cdot \text{HNO}_3 \cdot 8\frac{1}{2}\text{H}_2\text{O}$, which is less soluble than the normal nitrate. G. Malquori's study of the ternary system: $\text{Fe}(\text{NO}_3)_3\text{--HNO}_3\text{--H}_2\text{O}$, at 25° , is summarized in Fig. 685. He did not obtain the tetranitrate, but observed, as solid phases, the hexahydrate and the enneahydrate.

According to J. M. Ordway, the *enneahydrate*, $\text{Fe}(\text{NO}_3)_3 \cdot 9\text{H}_2\text{O}$, is deposited from soln. containing $\text{Fe}(\text{NO}_3)_3 \cdot 9\text{H}_2\text{O} + n(2\text{HNO}_3 \cdot 3\text{H}_2\text{O})$. The range of stability is

indicated in F. K. Cameron and W. O. Robinson's diagram, Fig. 684, *i.e.* in soln. containing 30 to 45 per cent. N_2O_5 , at 25° . G. Malquori obtained the enneahydrate from soln. with between 5.99 per cent. Fe_2O_3 , 45.84 per cent. N_2O_5 , and 9.25 per cent. Fe_2O_3 , 46.48 per cent. N_2O_5 . S. Hausmann, and C. F. Schönbein obtained the *hexahydrate*, $Fe(NO_3)_3 \cdot 6H_2O$, by evaporating the aq. soln. to a syrup, and adding half its vol. of nitric acid; R. Wildenstein, by allowing a conc. soln. of iron in nitric acid to stand for 18 months; A. Scheurer-Kestner, by crystallization from the mother-liquor after the separation of the enneahydrate; J. M. Ordway, by heating the enneahydrate until 14 per cent. of water has been expelled, and then adding nitric acid, or by cooling a soln. of a mol. of the fused enneahydrate with 4 mols. of nitric acid; and G. Malquori, by the action of conc. nitric acid on a sat. soln. of the enneahydrate in nitric acid of sp. gr. 1.52. According to J. M. Ordway, the salt is best obtained from a soln. with $Fe(NO_3)_2 \cdot 6H_2O + nHNO_3 \cdot H_2O$ —if more water is present, the enneahydrate appears, and if less, the soln. crystallizes with difficulty. G. Malquori said that at 25° , the salt is stable with soln. containing 9.25 to 9.28 per cent. Fe_2O_3 and 46.48 to 48.88 per cent. N_2O_5 —*vide supra*, Fig. 684. A. Ditte reported a *trihydrate*, $Fe(NO_3)_3 \cdot 3H_2O$, to be formed by evaporating a soln. containing a large excess of nitric acid; saturating the syrupy liquid with $HNO_3 \cdot H_2O$ at 60° ; and draining the crystals on a porous tile. A. Scheurer-Kestner could not confirm the existence of this salt; he said that the *monohydrate*, $Fe(NO_3)_3 \cdot H_2O$, separates from a soln. supersaturated on the water-bath and then cooled to 0° . J. M. Ordway could not prepare the monohydrate. The hydrates were studied by E. N. Gapon.

The physical properties of ferric nitrate.—The enneahydrate was said by C. F. Schönbein, and E. Schaer to furnish pale lavender-blue, amethyst-blue, or purple-coloured rhombic prisms. If pure, the salt is colourless. When heated the colourless salt appears yellow or orange, but on cooling, it becomes colourless again. J. M. Ordway said that the crystals are probably monoclinic, and H. Frey, rhombohedral. N. I. Surgunoff, and B. Lambert and J. C. Thomson obtained colourless or white crystals, which, according to N. I. Surgunoff, are monoclinic with the axial ratio $a : b : c = 1.1296 : 1 : 1.9180$, and $\beta = 131^\circ 31'$. K. P. Grinakowsky thought that the crystals occur in two modifications. R. Wildenstein, and J. M. Ordway said that the hexahydrate forms water-clear, cubic crystals; and S. Hausmann, and A. Scheurer-Kestner said that the hexahydrate forms colourless prisms. A. Ditte also said that the trihydrate furnishes colourless needles; and A. Scheurer-Kestner, that the monohydrate appears as a colourless, crystalline mass. C. Leenhardt studied the speed of crystallization of the hydrate.

According to J. M. Ordway, the crystals of the enneahydrate have a **specific gravity** of 1.6835 at 21° , and when melted and supercooled to 21° , the sp. gr. is 1.6712. K. P. Grinakowsky found the sp. gr. of the undercooled molten enneahydrate to be, at $\theta/4^\circ$:

Sp. gr.	0.2°	9.7	20.7°	50.6°	65.2°
	1.7159	1.7064	1.6979	1.6599	1.6429

B. Franz gave for the sp. gr. of aq. soln. of the salt at $17.5/4^\circ$:

$Fe(NO_3)_3$.	5	10	20	30	40	50	60	65 per cent.
Sp. gr.	1.0398	1.0770	1.1612	1.2622	1.3746	1.4972	1.6572	1.7532

Some observations were made by J. Traube, A. Hauke, F. K. Cameron and W. O. Robinson, A. Heydweiller, C. E. Richards and R. W. Roberts, G. Piaggese, G. T. Gerlach, and H. C. Jones and F. H. Getman. According to B. Cabrera and E. Moles, the sp. gr., at $19/4^\circ$, of soln. with:

$Fe(NO_3)_3$	0.0129	0.0534	0.0584	0.1157	0.2204 millimol per litre.
Sp. gr.	1.0029	1.0087	1.0098	1.0209	1.0419

P. F. Gaehr expressed the relation between the sp. gr., D , and the percentage concentration, C , by $\log_{10} D = aC$, where a is a constant. F. K. Cameron and

W. O. Robinson measured the sp. gr. of soln. of ferric oxide in nitric acid of various concentrations; and B. Cabrera and E. Moles, the effect of nitric acid on the sp. gr. of soln. of ferric nitrate. J. Traube discussed the mol. solution vol.

M. Torre measured the **diffusion**, D , of soln. of ferric nitrate of concentration C grms. $\text{Fe}(\text{NO}_3)_3$ per 100 c.c., by the changes in concentration at different temp., in 24 hrs.:

	$C=0.804$			$C=0.320$			$C=0.160$		
	30°	40°	50°	30°	40°	50°	30°	40°	50°
D	0.290	0.349	0.407	0.114	0.134	0.161	0.059	0.067	0.081

K. P. Grinakowsky measured the **surface tension**, σ dynes per cm., the **molar surface energy**, $\sigma VM^{\frac{2}{3}}$ —1. 13, 22—and the temp. coeff. of the molar surface energy of undercooled molten enneahydrated ferric nitrate, and found:

	0.5°	9.6°	20.7°	50.6°	65.3°
σ	70.05	69.42	68.75	66.18	63.35
$\sigma VM^{\frac{2}{3}}$	4240.0	4217.0	4188.0	4105.3	3947.1
$d(\sigma VM^{\frac{2}{3}})/d\theta$	—	2.55	2.65	2.76	10.76

He also found the **viscosity** of the undercooled enneahydrate at 0.3°, 20.6°, and 50.5° to be respectively 6.0336, 1.0653, and 0.2234 grm. per cm. per sec. H. C. Jones and co-workers found the mol. **lowering of the freezing-point**, Δ , of soln. with C mols per litre to be:

C	0.0748	0.1496	0.4488	1.0472	1.4960
Δ	6.39	6.37	7.63	10.92	14.30

Enneahydrated ferric nitrate, like $\text{Cr}(\text{NO}_3)_3 \cdot 9\text{H}_2\text{O}$, and $\text{Al}(\text{NO}_3)_3 \cdot 9\text{H}_2\text{O}$, shows a greater lowering of the f.p. than is the case with the hexahydrated nitrates of magnesium, zinc, cobalt, and nickel; and it is four or five times as great as the value calculated on the assumption that the solvent and solute are independent. J. S. Anderson observed that the enneahydrate smells of nitric acid; A. Scheurer-Kestner, that some nitric acid is lost at 50°—C. Leenhardt said at 80°; and J. M. Ordway found that about half its nitric acid is lost at 100° and a dry, deliquescent, dark brown powder remains. According to C. Montemartini and E. Vernazza, the dehydration of ferrous nitrate hexahydrate at the ordinary temp. in an atmosphere of carbon dioxide is accompanied by evolution of nitric oxide, and oxidation of the iron: $3\text{Fe}(\text{NO}_3)_2 + 7\text{H}_2\text{O} \rightarrow 3\text{Fe}(\text{OH})_3 + 5\text{HNO}_3 + \text{NO}$. Decomposition in boiling aq. soln. in an atmosphere of carbon dioxide, is at first slow with formation of a reddish precipitate; it then suddenly becomes violent and continues to completion according to the above scheme. The preliminary period is shorter for more concentrated solutions or on addition of nitric or nitrous acid, but no definite relation between concentration and the formation of nitrogen dioxide, nitrous oxide, ammonia, etc., was found. The solid product is the hydrate, $\text{Fe}_2\text{O}_3 \cdot \text{H}_2\text{O}$. S. U. Pickering found that in sunlight, acid vapours are given off at ordinary temp., but they are re-absorbed in darkness. By repeatedly heating the salt above its m.p., K. P. Grinakowsky noticed that the salt is decomposed; F. K. Bell and W. A. Patrick, that with 6 to 8 hrs' heating at 120°, a dry, red basic nitrate is formed; and J. M. Ordway, that at a red-heat all the nitrate is lost, and ferric oxide remains. J. M. Ordway said that the **melting-point** of the enneahydrate is 47.2°; and K. P. Grinakowsky, 50.1°. J. M. Ordway noted that the molten salt remains as a clear, dark red liquid down to 21°. S. Hausmann said that the hexahydrate melts at 35°; C. F. Schönbein gave 50°; and J. M. Ordway, between 35° and 40°. K. P. Grinakowsky, and C. Leenhardt studied the **rate of crystallization** of the undercooled enneahydrate. J. M. Ordway gave 125° for the **boiling-point** of the enneahydrate.

M. Berthelot gave for the **heat of formation** $(\text{Fe}, \frac{3}{2}\text{N}_2, \frac{9}{2}\text{O}_2, \text{Aq.}) = 157.15$ Cals.; and for $\text{Fe}_2\text{O}_3 \cdot \frac{9}{2}\text{H}_2\text{O} + 6\text{HNO}_3(\text{soln.}) = 2\text{Fe}(\text{NO}_3)_3(\text{soln.}) + 35.4$ Cals., and J. Thomsen, 33.95 Cals. J. Thomsen found for the reaction in soln., $3\text{Ba}(\text{NO}_3)_2 + \text{Fe}_2(\text{SO}_4)_3 = 2\text{Fe}(\text{NO}_3)_3 + 3\text{BaSO}_4 + 25.776$ Cals. M. Berthelot gave -9.0 Cals. per mol. for

the **heat of solution** of the enneahydrate; and he said that the **heat of dilution** changes with age, because 12 litres of a fresh soln. of a mol of the salt in 6 litres absorbed 1.1 Cals. when diluted with 30 litres of water, but in 3-weeks-old soln., absorbed only 1.05 Cals.—this does not amount to much, after all. The negative heat of soln. is characteristic of **freezing mixtures**, and A. Scheurer-Kestner found that by the dissolution of 2 parts of the enneahydrate in 1 part of water, the temp. is lowered 18.5°.

A. Hauke measured the **index of refraction**, and found for a soln. with 16.65 per cent. $\text{Fe}(\text{NO}_3)_3$, $\mu = 1.3649$ for Na-light, 1.3673 for Tl-light, and 1.3625 for C-light; and for the relation between the **wave-length**, λ , of light, and the refractive index of a soln. with 0.996 gm. of water per c.c. of soln., at 17°, C. E. Richards and R. W. Roberts gave:

λ . . .	5893	5780	5461	5330	5218	5105
μ . . .	1.3797	1.3804	1.3818	1.3827	1.3836	1.3868

and for soln. with varying **concentration**, having C mol of the salt per litre, at 0°, H. C. Jones and F. H. Getman observed with Na-light:

C . . .	0.0748	0.1496	0.04488	0.7480	1.0470	1.4960
μ . . .	1.32689	1.33191	1.34536	1.35797	1.37075	1.38873

G. Limann found for the refractive index of soln. with C equivalents of the salt per litre, at 18°:

C . . .	0	0.5	1	2	4
μ { $H\alpha$ -line . . .	1.33139	1.33858	1.34562	1.35946	1.38635
D -line . . .	1.33322	1.34054	1.34769	1.36178	1.38917
$H\beta$ -line . . .	1.33737	1.34504	1.35248	1.36713	1.39571
R . . .	35.93	35.90	35.89	35.78	35.6

Observations were also made by A. Heydweiller. The **molecular refraction**, R , obtained by A. Hauke, for a 16.65 per cent. soln. for the C -line, is 73.0; and G. Limann gave 35.84 at 18° for Na-light; and the results by A. Heydweiller are indicated above. A. Heydweiller, and G. Limann calculated values for the dispersion. A. Heydweiller discussed the relation between the optical properties and the electrical conductivity of the soln.

The colour of aq. soln. of ferric nitrate is conditioned by hydrolysis—*vide infra*. According to A. Byk and H. Jaffe, the **absorption spectrum** shows a band in the ultra-violet, and it is displaced in the direction of the short wave-lengths by dilution, or by the addition of nitric acid. J. S. Anderson found for the extinction coeff., k , of soln. with C mols of $\text{Fe}(\text{NO}_3)_3 \cdot 9\text{H}_2\text{O}$ per litre:

λ . . .	4340	4990	5470	6020	6870	7460	8370	9680	11,750
k { $C=2.0$. . .	7.3	2.25	0.70	0.16	0.17	0.25	0.32	0.13	0.01
$C=0.2$. . .	10.6	4.04	0.82	—	—	0.37	0.95	0.21	0.04

for the effect of varying the concentration of the soln.:

	$\lambda=4530$					$\lambda=6530$		
C . . .	2.0	1.4	0.8	0.2	0.02	2.0	1.4	0.8
k . . .	5.57	5.95	6.48	10.49	13.15	0.14	0.15	0.16

Observations were also made by R. A. Houstoun, R. A. Houstoun and C. Cochran, T. Ewan, C. E. Richards and R. W. Roberts, and R. A. Morton and R. W. Riding.

M. E. Verdet found that the **magnetic rotatory power**—i.e. the magnetic rotation of the plane of polarization of light—is smaller for soln. of ferric nitrate than it is for water; the effect becomes almost zero for very conc. soln., but it does not attain a negative value. C. E. Richards and R. W. Roberts observed that the sp. rotation, ω , and the value calculated for $\text{Fe}(\text{NO}_3)_3$, of a soln. with 0.996 gm. of water per c.c. of soln., at 20°, in a magnetic field of 13,510 gauss, and light of wave-length, λ :

λ . . .	5893	5780	5461	5330	5218	5105
ω . . .	0.0085	0.0090	0.0096	0.0096	0.0099	0.0104
$\omega\text{-Fe}(\text{NO}_3)_3$. . .	-0.0050	-0.0050	0.0061	0.0069	0.0073	0.0077

There is an absorption band for $\lambda=5350$. The value of ω increases with a rise of temp. P. K. Pillai, E. Miescher, and F. Allison and E. J. Murphy studied the magneto-optic properties.

M. Schneider could detect no reduction of aq. soln. of ferric nitrate in **sunlight**, but W. H. Ross, and O. Baudisch and E. Mayer observed that in **ultra-violet light**, reduction to ferrous nitrate occurs with the evolution of oxygen. S. U. Pickering observed that the ennehydrate in sunlight gives off acid fumes which are re-absorbed in darkness.

The **electrical conductivity** of aq. soln. of ferric nitrate was measured by H. C. Jones and co-workers, and by A. Heydweiller. H. C. Jones and C. A. Jacobson gave for the mol. conductivity of soln., μ , with a mol of the nitrate in v litres :

v	2	8	16	32	128	512	1024	2048
$\left\{ \begin{array}{l} 0^\circ \\ 10^\circ \\ 25^\circ \\ 35^\circ \end{array} \right.$	$\left\{ \begin{array}{l} 97.68 \\ 128.1 \\ 181.6 \\ 220.7 \end{array} \right.$	$\left\{ \begin{array}{l} 132.2 \\ 185.7 \\ 266.5 \\ 328.2 \end{array} \right.$	$\left\{ \begin{array}{l} 150.7 \\ 202.7 \\ 295.3 \\ 364.3 \end{array} \right.$	$\left\{ \begin{array}{l} 171.4 \\ 233.7 \\ 342.6 \\ 422.6 \end{array} \right.$	$\left\{ \begin{array}{l} 199.5 \\ 271.7 \\ 399.4 \\ 491.4 \end{array} \right.$	$\left\{ \begin{array}{l} 371.3 \\ 408.7 \\ 705.7 \\ 927.0 \end{array} \right.$	$\left\{ \begin{array}{l} 490.9 \\ 571.4 \\ 877.7 \\ 1116.5 \end{array} \right.$	$\left\{ \begin{array}{l} 585.2 \\ 693.5 \\ 961.6 \\ 1183.0 \end{array} \right.$

A. A. Noyes and B. F. Brann showed that the conductivity of a freshly-prepared soln. of $0.1N\text{-Fe(NO}_3)_3$ changes in some weeks at ordinary temp., or in a couple of hours at 50° to 55° . A. Heydweiller gave 123 for the limiting value of the eq. conductivity at 18° ; and H. C. Jones and F. H. Getman, 190.6 for the limiting value of the mol. conductivity at 0° . A. Heydweiller discussed the relation between the optical properties and the eq. conductivity of aq. soln. of ferric nitrate. H. C. Jones and F. H. Getman calculated for the percentage **degree of ionization**, α , and obtained for the mol. conductivity of soln. with a mol. of the salt in v litres at 0° :

v	0.67	0.74	0.95	1.34	2.23	2.34	6.68	13.37
μ	43.2	48.2	63.4	82.0	102.0	117.2	136.4	152.5
α	22.6	25.3	33.3	43.0	53.5	61.5	71.6	80.0

H. C. Jones and C. A. Jacobson observed that the value of α increases with a rise of temp., owing to hydrolysis. H. C. Jones and F. H. Getman calculated values for the **solvation** or **degree of hydration** of ferric nitrate in aq. soln. For soln. with C mols of $\text{Fe(NO}_3)_3$ per litre, $[\text{H}_2\text{O}]$, represented the number of mols in combination with a mol of salt if a litre of the soln. at the given concentration, contained 1000 grms. of water :

C	1.4960	1.3464	1.0472	0.7480	0.4488	0.2992
$[\text{H}_2\text{O}]$	28	29	33	37	43	37

As indicated above, the salt is hydrolyzed in aq. soln. The degree of hydrolysis is dependent on the conc., the age, the temp., the acidity, and the presence of other substances in the soln. The progress of the hydrolysis is shown by the changes of colour which occur, for this is determined by the presence of colloidal hydrated ferric oxide: $\text{Fe(NO}_3)_3 + 3\text{H}_2\text{O} \rightleftharpoons \text{Fe(OH)}_3 + 3\text{HNO}_3$, so that the colour changes through yellow, brown, and red, after which, a turbidity appears. Thus, S. U. Pickering observed that the colour of the aq. soln. increases in intensity with progressive dilution until a maximum is attained, after which the colour becomes paler with dilution. G. Wiedemann gave for the percentage degree of hydrolysis, H , of soln. with C grms. of $\text{Fe(NO}_3)_3$ per 100 c.c. at 20° :

C	50.03	37.51	24.99	18.75	12.47	6.24
H	12.0	13.9	14.4	14.0	14.9	17.7

U. Antony and G. Gigli found for soln. 10 days old :

C	50 to 6.7	4.0	2.0	0.5	0.2	0.05	0.02	0.005	0.004
H	7	13	16	26	30	44	55	14.9	17.7

The formation of colloidal hydrated ferric oxide is shown by the fact that sodium chloride precipitates ferric hydroxide, and that potassium ferrocyanide gives no

blue coloration in such solutions ; in less dilute solution, to which ferrocyanide has been added, the blue colour gradually increases in intensity owing to the continued re-formation of the ferric nitrate. Aq. solutions of ferric nitrate containing less than 0.1 per cent. are quite colourless, thus differing from other dil. soln. of ferric salts which are always coloured ; it is supposed that in such dil. ferric nitrate soln., basic ferric salts are not formed, but rather salts of pyronitric acid, $\text{H}_4\text{N}_2\text{O}_7$, or orthonitric acid, H_5NO_5 . Ferric orthonitrate and pyronitrate being simply products of hydrolysis of ferric nitrate, the reaction between all three salts and water is a reversible one ; the orthonitrate by further hydrolysis dissociates into ferric hydroxide and nitric acid. U. Antony and G. Gigli thus concluded that the successive stages of the hydrolysis are :

R. Weinland attributed the amethyst tint, observed by S. U. Pickering with conc. soln., to the formation of a pale red hexaquoferrous cation. J. S. Anderson showed that a soln. with over 0.8 mol of the nitrate per litre remained clear under conditions where a soln. with 0.2 mol per litre became turbid in a year, and with a soln. having 0.02 mol per litre, the precipitation of the hydrated ferric oxide was complete, and the soln. decolorized. The progress of the hydrolysis by colour-changes was also observed by U. Antony and G. Gigli, and, as indicated above, by A. A. Noyes and B. F. Brann. C. F. Schönbein observed that by raising the temp. of an aq. soln. of ferric nitrate, the colour deepens as it passes from yellow to brown to red, and that when the soln. is cooled the liquid becomes paler in tint. Analogous observations showing that the progress of the hydrolysis is favoured by raising the temp. were made by F. Beilstein and R. Luther, M. Berthelot, T. Cohen, E. J. Houstoun, S. U. Pickering, E. Schaer, E. A. Schneider, and A. A. Noyes and B. F. Brann. G. Wiedemann observed almost a linear relation between the percentage degree of hydrolysis, H , and the temp. between 10° and 60° for a soln. of the nitrate with 1.155 grms. Fe in 10 c.c. :

	6°	15°	20.5°	25°	31.5°	41°	51°	55.3°	62°
H	9.6	10.3	12.5	13.5	15.5	16.6	18.7	19.3	21.4

According to J. M. Ordway, and A. Scheurer-Kestner, the brown aq. soln. of ferric nitrate becomes colourless if a little nitric acid be added. A similar observation was made by A. A. Noyes and B. F. Brann. F. K. Cameron and W. O. Robinson said that the brown colour disappears when a mol of HNO_3 is present per mol of $\text{Fe(NO}_3)_3$, and S. U. Pickering said that when 1.2 to 1.8 mols of HNO_3 are present per gram-atom of iron, the dil. soln. is yellow ; with 3 to 20 mols of nitric acid, the colour is lemon-yellow. G. Wiedemann examined the effect of nitric acid on the degree of hydrolysis of ferric nitrate soln. C. F. Schönbein, and E. Schaer observed the effect of various additions on the colour-changes of the soln. ; G. Wiedemann, the degree of hydrolysis of basic nitrate in aq. soln. ; and S. Miyamoto, the decomposing action of the silent discharge.

A. A. Groening and H. P. Cady measured the **decomposition voltage** of soln. of ferric nitrate in water and in liquid ammonia, and obtained 1.02 and 1.19 volts respectively ; and the metal over-voltages are respectively 0.15 and -0.8 volt. A. Schukareff observed a **magnetochemical effect** in the electrolysis of a soln. of ferric nitrate with platinum electrodes when the cathode is in a magnetic field, but not so with the anode in a magnetic field.

M. Faraday found enneahydrated ferric nitrate to be paramagnetic ; and A. Quartaroli showed that if the aq. soln. is not too dilute, it also is paramagnetic, but very dilute soln. are diamagnetic. The concentration of the soln. where the diamagnetism of water just neutralizes the paramagnetism of the ferric nitrate is 2.94 grms. Fe per litre. Observations on the **magnetic properties** of the soln. were made by J. Plücker, and G. Wiedemann. J. S. E. Townsend gave 62×10^{-6}

mass unit for the **magnetic susceptibility** of the aq. soln. at 10° ; O. Liebknecht and A. P. Wills, 56×10^{-6} at 18° ; and G. Jäger and S. Meyer, 46×10^{-6} at 18° . G. Jäger and S. Meyer measured the effect of variations in the field-strength between 10,000 and 18,000 gauss, and J. S. E. Townsend, between 1 and 9 gauss, and observed no perceptible influence on the susceptibility. L. A. Welo's results for the solid and fused salt are indicated in Fig. 580. B. Cabrera and E. Moles gave for the sp. and the at. susceptibility of aq. soln. of ferric nitrate, between 16.6° and 18.3° :

$\text{Fe}(\text{NO}_3)_3$.	.	0.5304	1.292	1.412	2.837	5.530 per cent.
Specific $\chi \times 10^6$.	.	-0.4378	-0.03579	0.03014	0.8359	2.2933
Atomic $\chi \times 10^6$.	.	12,755	12,665	12,730	13,145	13,550

The results for soln. with 1.285 grms. $\text{Fe}(\text{NO}_3)_3$ per 100 grms. of soln. containing free nitric acid in the proportion q mol HNO_3 : mol. $\text{Fe}(\text{NO}_3)_3$:

q	.	.	0.1876	0.3377	0.8646	1.3371	2.714
$\chi \times 10^6$.	.	0.0860	0.2227	0.6172	0.6750	0.7465

Observations were also made by G. Piaggese, and A. Quartaroli; the last-named gave for the mol. susceptibility of soln. with a mol of salt in v litres, at 18° :

v	.	.	10	100	250	500	1,000
$\chi \times 10^6$.	.	12,789	12,272	11,859	11,860	11,545

J. S. E. Townsend found that at 10° , in a field of 1 to 9 gauss, there is a linear relation between the susceptibility, and the degree of dilution. G. Wiedemann, G. Piaggese, and A. E. Oxley observed a linear relation between the susceptibility and temp. G. Piaggese found for soln. of the percentage concentration C , with a field of intensity H gauss:

$\chi \times 10^6$	$H=4100; C=42.819$				$H=7460; C=7.325$			
	24.2°	40.3°	71.5°	84.7°	23.7°	41.2°	63.5°	85.4°
	27.521	26.289	24.667	23.185	3.247	3.077	2.898	2.703

H. Mosler observed that the temp. coeff. with soln. containing 12.1, 16.4, 21.2, and 28.2 per cent. $\text{Fe}(\text{NO}_3)_3$, are respectively -0.00273, -0.00287, -0.00286, and -0.00287, between 0° and 40° ; whilst G. Piaggese gave for soln. with 7.32, 19.51, and 42.82 per cent. $\text{Fe}(\text{NO}_3)_3$, the respective values -0.00287, -0.00285, and -0.00276 between 23° and 85° . Observations were also made by G. Jäger and S. Meyer. According to L. A. Welo, the magnetic susceptibilities of solid and liquid enneahydrate are summarized in Fig. 580. The Curie constants, $C=\chi(T-\theta)$, for the solid are, $C=4.25$, and $\theta=0^\circ$; and for the liquid, $C=1.78$, and $\theta=164^\circ$. B. Cabrera and E. Moles, and A. Quartaroli made estimates of the **magneton number** for ferric nitrate in aq. soln.

The chemical properties of ferric nitrate.—S. Miyamoto said that in the silent electric discharge, in hydrogen, the hydroxide, nitric oxide, nitrogen dioxide, and ammonium nitrate and nitrite are formed. W. Ipatéeff and A. I. Kisseleff, and W. Ipatéeff found that **hydrogen** at about 200 atm. press. acts on a soln. of iron nitrate precipitating hydrated ferric oxide, or a mixture of ferrous and ferric oxides; metallic iron was not formed even at 360° . C. F. Schönbein noticed the reduction of a soln. of ferric nitrate by nascent hydrogen; and F. F. Runge, its reduction by zinc amalgam. H. Frey found the enneahydrate to be very deliquescent in **air**; and A. Scheurer-Kestner, and N. I. Surgunoff added that a brown liquid is produced which readily decomposes when heated, for it gives off nitric acid fumes at 50° . C. F. Schönbein observed that the hexahydrate deliquesces to a honey-yellow liquid. J. M. Ordway, A. Scheurer-Kestner, and F. K. Cameron and W. O. Robinson found that the enneahydrate dissolves in **water** in all proportions, forming a brown or yellowish-brown soln.; but G. Malquori added that the solubility at 25° is 46.57 per cent.—*vide* Figs. 686 and 689, $\text{Fe}(\text{NO}_3)_3$. J. M. Ordway observed that the hexahydrate readily takes up 3 mols. of water to form the

enneahydrate; C. F. Schönbein added that the hexahydrate dissolves in water in all proportions. The relations of the nitrate with water have been discussed in connection with the solubility of the salt; and also in connection with the hydrolysis of aq. soln. V. L. Bohson, and I. S. Teletoff and V. M. Simonova studied the catalytic action of ferric nitrate on **hydrogen dioxide**—*vide supra*, ferric chloride.

Many **basic salts** have been reported, but F. K. Cameron and W. O. Robinson could find none; and they consider to be solid soln. all the basic nitrates which have been reported; remembering their results with the basic ferric sulphates, it is possible that some of the basic nitrates which have been reported, or are yet to be reported as being formed under other conditions, may be chemical individuals. U. Antony and G. Gigli assumed that definite individuals are formed as intermediate products in the hydrolysis of aq. soln. of the nitrate—*vide supra*, the hydrolysis of this salt, and also in connection with the basic carbonates. A. Müller, and E. Lenssen regarded commercial *iron-liquor* as a soln. of basic nitrates. J. M. Ordway said that a mol. of N_2O_5 forms compounds with 1, 2, 3, 4, 5, 6, and 8 mols. of ferric oxide, and that they are soluble in water. These substances can be prepared as colloidal soln. by dissolving the calculated quantity of freshly-precipitated, hydrated ferric oxide in an aq. soln. of ferric nitrate. Soln. containing 6 mols. of ferric oxide to 1 mol. of N_2O_5 furnish precipitates, when treated with various salts—*e.g.*, sodium or ammonium chloride; potassium iodide or chlorate; sodium, calcium, zinc, or copper sulphate; potassium, sodium, ammonium, magnesium, barium, or lead nitrate; and barium or zinc acetate; but not by alcohol, lead or copper acetate, mercuric cyanide, silver nitrate, or arsenious acid. The phenomenon resembles the flocculation of colloids by electrolytes—*vide supra*, ferric chloride, and the hydrosol and hydrogel of hydrated ferric oxide.

Taking the mol. ratios in this order: $Fe_2O_3 : N_2O_5 : H_2O$, S. Hausmann reported what he regarded as 36:1:48; A. Béchamp, 12:1:0; A. Béchamp, S. Hausmann, and J. M. Ordway, 8:1:12; J. M. Ordway, 6:1:*n*; and also 5:1:*n*; J. J. Berzelius, P. Grouvelle, S. Hausmann, J. M. Ordway, C. F. Schönbein, and A. Scheurer-Kestner, 4:1:*n*; A. Scheurer-Kestner, and J. M. Ordway, 3:1:2; J. M. Ordway, 3:3:*n*; A. Benrath, J. M. Ordway, A. Piccini and F. M. Zucco, and A. Scheurer-Kestner, 2:1:1; J. M. Ordway, and A. Scheurer-Kestner, 1:1:*n*; J. M. Ordway, 2:3:*n*; G. Lemoine, J. M. Ordway, and A. Scheurer-Kestner, 1:2:*n*; and J. M. Ordway, 2:5:*n*.

C. F. Schönbein, and E. Schaer discussed the colour-changes which occur when **potassium bromide**, or **sulphur dioxide** is added to the aq. soln. C. F. Schönbein noted the reducing action of sulphur dioxide as well as of **selenium and tellurium hydrides**. A. W. Davidson found that the enneahydrate with 100 per cent. **sulphuric acid** forms yellowish-white, insoluble ferric sulphate. C. F. Schönbein, and E. Schaer discussed the colour-changes which occur when **ammonium chloride** is added to the aq. soln. H. Davy observed that a soln. of ferric nitrate absorbs little or no **nitric oxide**; and C. F. Schönbein observed that this gas reduces a soln. of ferric nitrate. W. Heldt, and E. S. Hedges found that with an increasing concentration of **nitric acid**, the solubility of the nitrate is reduced; J. M. Ordway found that 100 parts of nitric acid of sp. gr. 1.37 do not quite dissolve 5 parts of the enneahydrate at 15.6°. C. F. Schönbein observed that **phosphorus** slowly reduces a soln. of ferric nitrate; and similarly with **phosphine**; **arsenic, antimony, and bismuth** also reduce the soln., as does **stibine**. C. F. Schönbein, and E. Schaer discussed the colour-changes which occur on the addition of **arsenic trioxide** to a soln. of ferric nitrate.

When the soln. is shaken up with **carbon** powder, it is reduced forming ferrous nitrate and a basic ferric nitrate. C. F. Schönbein, and E. Schaer discussed the colour-changes which occur when **methyl** or **ethyl alcohol** is added to the aq. soln. A. Scheurer-Kestner observed that the enneahydrate forms a brown soln. with alcohol, but, added J. M. Ordway, the solution is incomplete. E. Schaer observed

that the soln. in 97 to 98 per cent. alcohol is not stable, and decomposes in a few weeks at ordinary temp. or when warmed, depositing a basic nitrate. A. Benrath observed that in the photochemical oxidation of alcohol by ferric nitrate, the ferric salt is not reduced to the ferrous state, but a basic ferric nitrate is precipitated. A. Naumann observed that the enneahydrate dissolves in **acetone** of sp. gr. 0.795. R. Weinland and co-workers, A. Rosenheim and P. Müller, and E. Späth discussed the action of **acetic acid** on the ennea- and hexahydrates; a complex salt appears to be formed. The complex salts were studied by R. Grünberg-Krasnowskaja, and R. Weinland and H. Hachenburg. C. F. Schönbein observed that the acid reduces a hot soln. of ferric nitrate, and that the reduction is incomplete in the cold; similar results were obtained with **formic, citric, tartaric, and uric acids**; C. F. Schönbein, and E. Schaer observed the effect of tartaric and citric acids on the hydrolysis of ferric nitrate. C. F. Schönbein observed that not only is **oxalic acid** not oxidized by soln. of ferric nitrate, but that the acid hinders the reduction of the nitrate by other organic and inorganic substances, but G. Lemoine said that the oxalic acid is oxidized with the evolution of carbon dioxide and nitrogen peroxide, and the formation of a precipitate of basic ferric nitrate and ferric oxide. U. Antony and G. Gigli discussed the action of **potassium ferrocyanide** on ferric nitrate. R. Weinland and A. Kissling studied the compounds formed with **quinoline**. G. Spacu obtained a complex with **benzidine**, and G. A. Barbieri, one with **urea**. C. F. Schönbein noted the reducing action of **creosote**, and **sugar**; and C. F. Schönbein, and E. Schaer, the decolorization of **indigo**; and the effect of **gum arabic** on the colour of the soln. J. Jettmar discussed the action of ferric nitrate soln. on **animal skins** in the tanning industry. I. Plotnikoff and K. Weber studied the action of the nitrate on **nicotine**; and W. Thomson and F. Lewis, on **india-rubber**.

C. F. Schönbein found that a soln. of ferric nitrate is slowly reduced by some **metals**—copper, silver, zinc cadmium, mercury, tin, lead, and iron; but the action with gold, palladium and platinum is uncertain. M. V. Dover, and A. A. Noyes and B. F. Brann represented the reaction with silver by: $\text{Ag} + \text{Fe}(\text{NO}_3)_3 \rightleftharpoons \text{AgNO}_3 + \text{Fe}(\text{NO}_3)_2$, which was also discussed by E. J. Shaw and M. E. Hyde. C. C. Palit and N. R. Dhar noticed that the presence of ferric nitrate retards the dissolution of mercury in nitric acid, but accelerates the action of the acid on copper, and silver. C. F. Schönbein found that the soln. of ferric nitrate is slowly reduced by **cuprous oxide**; and D. Vitali found that **silver oxide** results in the deposition of hydrated ferric oxide; A. Mailhe, that yellow, freshly-precipitated **mercuric oxide** is dissolved, and a basic mercuric nitrate, $\text{Hg}_2\text{O}(\text{NO}_3)_2 \cdot \text{H}_2\text{O}$, is precipitated; E. A. Schneider, that **aluminium hydroxide** is taken up in colloidal soln.; and J. M. Ordway, that **ferric hydroxide** is also taken up in colloidal soln. E. Kothny found that **cupric sulphide**, and **chalcopyrite** are not attacked by a soln. of ferric nitrate, but E. F. Anthon observed that with **lead sulphide** some iron sulphide is formed. According to E. M. Walton, and J. M. Ordway, when the enneahydrate is mixed with hydrated **sodium carbonate** or **hydrocarbonate**, there is a marked drop in temp.; and E. M. Walton, that when the enneahydrate is mixed with hydrated **calcium** or **sodium chloride**, the mixture liquefies, and there is an interchange of acid radicles.

G. Malquori's observations on the ternary system: $\text{KNO}_3\text{--Fe}(\text{NO}_3)_3\text{--H}_2\text{O}$, show that no **potassium ferric nitrate** is formed at 25° , but in the presence of nitric acid, potassium ferric nitrate, $2\text{KNO}_3 \cdot \text{Fe}(\text{NO}_3)_3 \cdot 4\text{H}_2\text{O}$, is formed as indicated below. The results are summarized in Figs. 686 and 687. G. Malquori studied the quaternary system: $\text{Fe}(\text{NO}_3)_3\text{--KNO}_3\text{--HNO}_3\text{--H}_2\text{O}$ at 25° , and observed the solid phases $\text{Fe}(\text{NO}_3)_3 \cdot 9\text{H}_2\text{O}$ and $\text{Fe}(\text{NO}_3)_3 \cdot 6\text{H}_2\text{O}$ with soln. having $\text{Fe}(\text{NO}_3)_3$, 28.02 per cent.: HNO_3 , 54.23; and H_2O , 17.75: the two hydrates and $2\text{KNO}_3 \cdot \text{Fe}(\text{NO}_3)_3 \cdot 4\text{H}_2\text{O}$ with soln. having $\text{Fe}(\text{NO}_3)_3$, 27.00; KNO_3 , 17.30; HNO_3 , 39.11; H_2O , 16.59: the enneahydrate and KNO_3 with $\text{Fe}(\text{NO}_3)_3$, 39.05; KNO_3 , 11.02; and H_2O , 49.03: the enneahydrate, potassium nitrate, and $\text{Fe}(\text{NO}_3)_3 \cdot 2\text{KNO}_3 \cdot 4\text{H}_2\text{O}$ with $\text{Fe}(\text{NO}_3)_3$,

24.91 ; KNO_3 , 26.50 ; HNO_3 , 26.71 ; and H_2O , 21.88 ; and $\text{Fe}(\text{NO}_3)_3 \cdot 2\text{KNO}_3 \cdot 4\text{H}_2\text{O}$ and KNO_3 with $\text{Fe}(\text{NO}_3)_3$, 7.80 ; KNO_3 , 43.95 ; HNO_3 , 46.15 ; and H_2O , 2.10. The lines mMn , nNn , and pP represent the systems $\text{Fe}(\text{NO}_3)_3$ - HNO_3 - H_2O , $\text{Fe}(\text{NO}_3)_3$ - KNO_3 - H_2O , and KNO_3 - HNO_3 - H_2O respectively. Sat. soln. of $\text{Fe}(\text{NO}_3)_3 \cdot 9\text{H}_2\text{O} + \text{Fe}(\text{NO}_3)_3 \cdot 6\text{H}_2\text{O}$ are represented by the line MA ; $\text{Fe}(\text{NO}_3)_3 \cdot 9\text{H}_2\text{O} + \text{KNO}_3$, by NB ; $\text{Fe}(\text{NO}_3)_3 \cdot 9\text{H}_2\text{O} + \text{Fe}(\text{NO}_3)_3 \cdot 2\text{KNO}_3 \cdot 4\text{H}_2\text{O}$, by AB ; $\text{Fe}(\text{NO}_3)_3$.

FIG. 686.—The Quaternary System : $\text{Fe}(\text{NO}_3)_3$ - KNO_3 - HNO_3 - H_2O , at 25° .

FIG. 687.—Equilibrium in the Ternary System : KNO_3 - $\text{Fe}(\text{NO}_3)_3$ - H_2O , at 25° .

$2\text{KNO}_3 \cdot 4\text{H}_2\text{O} + \text{KNO}_3$, by BC . Points A and B represent soln. sat. with respect to three salts ; and C represents the solubility of $\text{Fe}(\text{NO}_3)_3 \cdot 2\text{KNO}_3 \cdot 4\text{H}_2\text{O}$ in a sat. soln. of potassium nitrate in nitric acid of sp. gr. 1.52. H. L. Wells and A. P. Beardsley reported caesium ferric nitrate, $\text{CsNO}_3 \cdot \text{Fe}(\text{NO}_3)_3 \cdot 7\text{H}_2\text{O}$, to be formed at a rather low temp. in very conc. soln. of eq. proportions of the component salts in nitric acid. The pale yellow, deliquescent, prismatic crystals melt between 33° and 36° .

FIG. 688.—Equilibrium in the Ternary System : $\text{Al}(\text{NO}_3)_3$ - $\text{Fe}(\text{NO}_3)_3$ - H_2O , at 25° .

FIG. 689.—Equilibrium Conditions in the Quaternary System : KNO_3 - $\text{Al}(\text{NO}_3)_3$ - $\text{Fe}(\text{NO}_3)_3$ - H_2O , at 25° .

G. Malquori in his study of the ternary system : $\text{Al}(\text{NO}_3)_3$ - $\text{Fe}(\text{NO}_3)_3$ - H_2O , at 25° , observed no formation of an aluminium ferric nitrate ; the only solid phases observed were the two enneahydrates as illustrated in Fig. 688. No complex was observed in the quaternary system : KNO_3 - $\text{Al}(\text{NO}_3)_3$ - $\text{Fe}(\text{NO}_3)_3$ - H_2O , at 25° . The results are summarized in Fig. 689.

§ 50. The Ferrous Phosphates

In 1758, A. Cronstedt¹ referred to *calx martis phlogisto juncta*; in 1772, I. Eques a Born referred to *cæruleum berlinense natioum*; in 1783, J. B. L. Romé de l'Île, to *ochre martiale bleue* or *bleue de Prusse natif*; and in 1784, M. H. Klaproth, to *natürliche Berlinerblau*; A. G. Werner applied the term *vivianite*—after J. G. Vivian—to an earth which was afterwards shown to be the same as the *blue iron earth*, or *native prussian blue*. F. Mohs called it *Eisenglimmer*; A. Breithaupt, *Eisenphyllite*; E. F. Glocker, *Glaucosiderit*; T. Thomson, *mullicite*; and P. Berthier, *anglarite*. Analyses, etc., have been reported by M. H. Klaproth, R. Pattison, J. Bostock, J. Murray, L. N. Vauquelin, F. Stromeyer, R. Brandes, A. Vogel,

M. Segeth, P. Berthier, C. F. Rammelsberg, N. S. Maskelyne and W. Flight, W. Fisher, F. Kurlbaum, H. Struve, S. P. Popoff, K. von Muraközy, W. L. Dudley, W. Tjelouchin, J. Thiel, and C. Schmidt. The fresh mineral, not contaminated with impurities, has a composition closely approximating that of **ferrous orthophosphate**, $\text{Fe}_3(\text{PO}_4)_2 \cdot 8\text{H}_2\text{O}$, but as emphasized by C. F. Rammelsberg, vivianite, as it usually occurs in nature, is rather a mixture of different phosphates: $\text{Fe}_3(\text{PO}_4)_2 \cdot 8\text{H}_2\text{O} + n\text{Fe}_3\text{P}_4\text{O}_{19} \cdot 16\text{H}_2\text{O}$; S. P. Popoff also emphasized that the ferrous iron may be isomorphously replaced by calcium, manganese, or magnesium, $\text{R}_3(\text{PO}_4)_2 \cdot 8\text{H}_2\text{O}$, where R denotes ferrous iron, Mg, Mn, and Ca, and he called this complex *paravivianite*; and there are a number of specimens containing more or less ferric iron—*e.g.*, $\text{R}_0.\text{Fe}_2\text{O}_3.\text{P}_2\text{O}_5.7\text{H}_2\text{O}$, or *α -kertschenite*—after Kertsch, Crimea; and $5\text{R}_0.2\text{Fe}_2\text{O}_3.3\text{P}_2\text{O}_5.23\text{H}_2\text{O}$, or *β -kertschenite*. W. L. Dudley represented the composition of the mineral by a doubled formula; and S. P. Popoff the tripled formulæ:

Vivianite, or blue earth, occurs associated with pyrrhotite and pyrite in copper, and other metal veins. It occurs friable and crystallized in beds of clay, and sometimes associated with limonite or bog-iron ore. It also frequently occurs in cavities of fossils or buried bones. Thus, A. Lacroix² found it associated with fossil teeth near Bayonne, Basses Pyrénées; P. Gaubert, in mastodon bones, San Pablo, Guatemala; and W. L. Dudley found, near Edgeville, Kentucky, plant roots which were transformed almost completely into blue earth by a process of replacement. J. Schlossberger discussed the formation of blue earth by the action of organic matter, and mentioned that some iron nails found in the stomach of an ostrich were enveloped in black, organic matter, and after several days' exposure to the air became covered with blue spots owing to the formation of the blue phosphate. L. Gmelin added that a pit in a town had been filled for centuries with bones, wood, ferruginous gneiss, etc. Colourless crystals of vivianite were found on the carbonized pieces of wood, and likewise on the micaceous laminae of the gneiss, but not on the other materials; the crystals became blue on exposure to air. W. Haidinger found crystals of vivianite in the hollow of a bone in the skeleton of a miner found in an old working at Tarnowitz. E. V. Shannon found vivianite encrusting a fossil tusk in Idaho; and H. Kunz-Krause discussed its formation in arable soils. Other examples were recorded by F. Sandberger, J. Nicklès, N. Friedreich, N. J. Berlin, and M. Nitschmann. R. Warrington found that a soln. of calcium phosphate in carbonated water is completely decomposed by hydroxides

of iron and aluminium found in clays and soils. The formation of blue earth in peat, and moor soils, etc., was discussed by J. Stansfield, A. F. Wiegmann, F. Senft, K. Rördam, J. M. van Bemmelen, A. Gärtner, and G. Reinders. G. Tammann and H. O. von Samson-Himmelstjerna attributed the blue colour of some artificial preparations to the presence of a ferrous polyphosphate, not ferric phosphate.

C. F. Rammelsberg³ obtained a white precipitate of ferrous phosphate by adding sodium hydrophosphate to a soln. of a ferrous salt; and the composition of the precipitates was also investigated by G. C. Wittstein, and G. Jenzsch. J. M. van Bemmelen said that if a mixed soln. of 1 of ferrous sulphate, 12 of sodium hydrophosphate, and 1 of glacial acetic acid be kept some days at ordinary temp. out of contact with air, the **colloidal ferrous phosphate** first produced forms a sol with the acetic acid, which gradually deposits crystals of the *octohydrate* of ferrous phosphate, $\text{Fe}_3(\text{PO}_4)_2 \cdot 8\text{H}_2\text{O}$. E. Angelescu and G. Balanescu found that the simultaneous precipitation of iron and phosphoric acid is possible when the ratio Fe : P is greater than 2, and when the acidity p_{H} is less than 7. The temp. and the anion of the ferric salt are without effect on the precipitation. In alkaline soln., the phosphoric acid is not completely adsorbed. W. R. G. Atkins studied the effect of the acidity of the soln. on the composition of ferrous phosphate. H. Debray obtained the normal ferrous phosphate by heating the hydrophosphate with water in a sealed tube at 250° ; E. N. Horsford, by heating mixed soln. of sodium phosphate and ferrous sulphate in an atm. of carbon dioxide in a sealed tube; and E. J. Evans, by allowing a soln. of 2 parts sodium acetate, 10 parts of sodium phosphate, and 8 parts of ferrous sulphate to stand for several days out of contact with air, collecting the precipitate on a calico filter, and drying it at 40° . Small crystals develop if the precipitate be kept in contact with its mother-liquor for a week at 60° to 80° .

G. Cesaro prepared the salt by mixing soln. of ammonium ferrous sulphate and ammonium phosphate, dissolving the precipitate by adding hydrofluoric acid dropwise, and allowing the soln. to stand for a long time. In about 17 days, the small crystals which appear have the composition of vivianite. E. Weinschenk obtained colourless crystals by the action of ammonium hydrophosphate on a soln. of a ferrous salt in a sealed tube at an elevated temp. According to A. C. Becquerel, iron plates immersed in an aq. soln. of ammonium phosphate become covered with white crystalline ferrous phosphate; and if a cell be made up with a porous pot containing a soln. of copper sulphate and a copper rod as cathode, placed in a soln. of sodium phosphate with an iron rod as anode, on closing the circuit, white crystalline nodules of ferrous phosphate collect on the iron rod, and then quickly assume a blue colour on exposure to air.

H. Debray prepared the *monohydrate*, $\text{Fe}_3(\text{PO}_4)_2 \cdot \text{H}_2\text{O}$, as a dark green, crystalline powder, by heating the hydrophosphate, FeHPO_4 , with water at 250° . F. Müllbauer obtained the *trihydrate*, $\text{Fe}_3(\text{PO}_4)_2 \cdot 3\text{H}_2\text{O}$, as a mineral occurring in the phosphate deposits of Bavaria; and he called it **bauldaufite**—after M. Bauldauf. It is considered to be isomorphous with hydrated manganous phosphate. The light rose, or flesh-red monoclinic prisms have the axial ratios $a : b : c = 2.21 : 1 : 1.84$, $\beta = 133^\circ 18'$. The optical character is negative. H. Steinmetz gave the formula: $\text{R}_5\text{H}_2(\text{PO}_4)_4 \cdot 5\text{H}_2\text{O}$. P. Dwojtschenko, and S. P. Popoff described a yellow, colloidal phosphate approximating $3\text{Fe}_2\text{O}_3 \cdot 2\text{P}_2\text{O}_5 \cdot 17\text{H}_2\text{O}$, from the Crimea; it was called **bosphorite**. A. Gautier said that the *hexahydrate*, $\text{Fe}_3(\text{PO}_4)_2 \cdot 6\text{H}_2\text{O}$, is formed by the prolonged heating at 83° of finely-divided ferrous carbonate in suspension in an aq. soln. of ammonium phosphate; or if a soln. of ferrous carbonate in carbonic acid is heated with ammonium phosphate. The mineral vivianite could have been formed naturally by some such reaction, but at a lower temp., and during a longer period to account for the higher water-content. The *octohydrate*, $\text{Fe}_3(\text{PO}_4)_2 \cdot 8\text{H}_2\text{O}$, is represented by vivianite.

The mineral is often white when freshly dug up, but it afterwards turns green or blue on exposure to air. This is the case with the colourless crystals from

Delaware, Pennsylvania, observed by W. Fisher. This is taken to indicate that the blue colour is due to the presence of ferric phosphate. The colour deepens on prolonged exposure—*vide infra*. The streak, or powder, is at first colourless to bluish-white, soon changing to indigo-blue. In the extreme case, the powder becomes liver-brown. Vivianite may occur in prismatic crystals sometimes flattened parallel to the (100)-face; and the prismatic faces may be striated. The crystals may occur in stellate groups. Vivianite may form reniform or globular masses, and have a fibrous or earthy structure. The mineral may also occur as an incrustation. G. vom Rath gave for the axial ratios of the monoclinic prisms, $a : b : c = 0.74975 : 1 : 0.70153$, and $\beta = 75^\circ 34\frac{1}{2}'$; and G. Cesaro, $0.7488 : 1 : 0.7020$, and $\beta = 104^\circ 33\frac{1}{4}'$. Observations on the crystals were also made by W. H. Miller, B. Gildersleeve, F. Ulrich, S. Koch, G. Cesaro, A. des Cloizeaux, H. Buttgenbach, E. V. Shannon, and O. Mügge. The (010)-cleavage is nearly perfect; and the (100)-cleavage occurs in traces. The optical character is positive; and the optic axial angles are medium; according to A. des Cloizeaux, these angles are, for red-light, $2H_a = 80^\circ 26'$; $2H_0 = 121^\circ 19'$; $2E = 142^\circ 22'$; and $2V = 73^\circ 4'$; for yellow-light, $2H_a = 80^\circ 35'$; $2H_0 = 121^\circ 10'$; $2E = 143^\circ 14'$; and $2V = 73^\circ 10'$; and for violet-light, $2H_a = 80^\circ 54'$; $2H_0 = 120^\circ 52'$; $2E = 146^\circ 46'$; and $2V = 73^\circ 26'$. E. S. Larsen gave $2H_0 = 90^\circ 01'$, $2V_a = 83^\circ 17'$ for Na-light; N. H. Winchell, $2V = 73^\circ 10'$; and V. Rosicky, $2V = 73^\circ 71'$ to $73^\circ 20'$. M. Kuhara studied the tear-figures or percussion figures of vivianite.

C. F. Rammelsberg gave 2.58 to 2.68 for the sp. gr. of vivianite; S. P. Popoff, 2.66; C. Schmidt, 2.542. The observed results for the sp. gr. of vivianite range from 2.5° to 2.72. E. S. Larsen gave 2.670 to 2.693 at 18°. The mean can be taken as 2.65. V. Rosicky found 2.678 for the vivianite from Vladic, and 2.686 for that from Cornwall. T. L. Watson and S. D. Gooch gave 2.693 for the sp. gr. of vivianite from Florida. The hardness of the crystals is 1.5 to 2.0. N. S. Kurnakoff and I. A. Andreevsky found that the dehydration curve has arrests at 110° to 112° , 170° , 296° to 304° . R. Cusack gave 1114° for the m.p. T. L. Watson and S. D. Gooch gave for the refractive indices, $\alpha = 1.580$; $\beta = 1.598$, and $\gamma = 1.627$; E. S. Larsen gave $\alpha = 1.579$, $\beta = 1.603$, and $\gamma = 1.633$; H. Berman, $\alpha = 1.584$, $\beta = 1.600$, and $\gamma = 1.634$; N. H. Winchell, $\alpha = 1.5766$, $\beta = 1.6050$, and $\gamma = 1.6267$; and V. Rosicky, $\alpha = 1.5809$, $\beta = 1.6038$, and $\gamma = 1.6361$; F. Ulrich, T. L. Watson and S. D. Gooch, and A. Lacroix also made observations on the subject. R. Robl observed no luminescence in ultra-violet light.

Ferrous phosphate, vivianite, as indicated above, rapidly oxidizes on exposure to air, thereby losing its white colour, and, passing through deepening shades of blue, finally becoming brown beraunite, or something similar. Oxidation occurs rapidly when the mineral is finely ground. A. Gärtner analyzed vivianite in three forms—(i) freshly dug; (ii) after a month's exposure; and (iii) after three months' exposure, and found:

	MgO	CaO	FeO	Fe ₂ O ₃	P ₂ O ₅	Loss	Organic and sand	CO ₂
(i) . . .	—	3.69	39.76	3.07	25.82	6.64	20.02	—
(ii) . . .	0.11	2.59	25.70	6.10	17.70	35.07	9.55	—
(iii) . . .	0.09	2.40	19.55	18.11	12.02	26.05	14.48	7.3

The subject was further considered by G. Tschermak, T. L. Watson, M. Oknoff, and S. P. Popoff. The last-named considered that the stages in the oxidation of paravivianite, $(\text{Mg,Ca,Mn,Fe})_3(\text{PO}_4)_2 \cdot 8\text{H}_2\text{O}$, are represented β -kertschenite, α -kertschenite, and oxykertschenite, whose graphic formulæ have been previously indicated. F. Cornu observed that moist vivianite has a strong acidic reaction. The salt is said to be insoluble in water, but F. K. Cameron and L. A. Hurst showed that the phosphates of iron, aluminium, and calcium are hydrolyzed by water which becomes more acidic, and a basic phosphate remains. S. R. Carter and N. H. Hartshorne studied the ternary system: $\text{FeO}-\text{P}_2\text{O}_5-\text{H}_2\text{O}$, at 70° , with between 7.38 and 57.51 per cent. of phosphoric acid. Within this range, the stable phases are: $2\text{FeO} \cdot \text{P}_2\text{O}_5 \cdot 5\text{H}_2\text{O}$, or $\text{FeHPO}_4 \cdot 2\text{H}_2\text{O}$; $2\text{FeO} \cdot \text{P}_2\text{O}_5 \cdot 3\text{H}_2\text{O}$, or $\text{FeHPO}_4 \cdot \text{H}_2\text{O}$;

and $\text{FeO} \cdot \text{P}_2\text{O}_5 \cdot 4\text{H}_2\text{O}$, or $\text{Fe}(\text{H}_2\text{PO}_4)_2 \cdot 2\text{H}_2\text{O}$. No vivianite appears. Expressing the concentration of the liquid phase in percentages, the ranges of stability of the solid phases are :

FeO . . .	2.76	4.38	5.54	7.71	9.12	11.9	10.5	6.29	3.15
P_2O_5 . .	7.38	12.06	15.1	21.6	24.29	36.99	38.86	46.61	57.51
	$\text{FeHPO}_4 \cdot 2\text{H}_2\text{O}$			$\text{FeHPO}_4 \cdot \text{H}_2\text{O}$			$\text{Fe}(\text{H}_2\text{PO}_4)_2 \cdot 2\text{H}_2\text{O}$		

Returning to vivianite, J. I. Pierre said that 1 part of ferrous phosphate is soluble in 1000 parts of water containing more than 1 vol. of carbon dioxide. J. M. van

Bemmelen found that hydrogen dioxide also oxidizes vivianite to a product resembling beraunite. W. Kangro and R. Flüge observed that at 900° , chlorine gas removed 96.7 per cent. of the iron from vivianite, but no phosphorus was removed. L. Cambi and A. Cagnasso studied the absorption of nitric oxide by ferrous hydrophosphate suspended in water at 0° , and noted that as the nitric oxide is reduced to nitrous oxide, some hyponitrite is produced. W. Wardlaw and co-workers found that ferrous phosphate in conc. soln. of phosphoric acid is considerably oxidized by sulphur dioxide; $4\text{Fe}(\text{H}_2\text{PO}_4)_2 + 4\text{H}_3\text{PO}_4 + \text{SO}_2 = 4\text{Fe}(\text{H}_2\text{PO}_4)_3 + 2\text{H}_2\text{O} + \text{S}$. According to E. J. Evans, ferrous phosphate is

FIG. 690.—Equilibrium in the Ternary System: $\text{FeO}-\text{P}_2\text{O}_5-\text{H}_2\text{O}$, at 70° .

soluble in acids, and in aq. ammonia; and, according to R. H. Brett, it dissolves in soln. of ammonium salts. F. Ephraim observed that no iron nitride is formed when sodamide is heated with ferrous phosphate. H. C. Bolton observed that it is soluble in cold citric acid; and J. I. Pierre found 1 part of ferrous phosphate is soluble in 560 parts of water containing $\frac{1}{566}$ th part of acetic acid, and 1 part of the phosphate dissolves in 1666 parts of water containing 150 parts of ammonium acetate. J. Spiller found that the presence of sodium citrate prevents the precipitation of ferrous phosphate. According to A. Naumann, the phosphate is insoluble in acetone. Ferrous phosphate is soluble in an excess of a soln. of a ferrous salt. A boiling soln. of potassium hydroxide dissolves out the phosphoric acid from vivianite. W. Heike represented the reaction with calcium oxide: $\text{Fe}_3(\text{PO}_4)_2 + 4\text{CaO} \rightleftharpoons \text{Ca}_4\text{P}_2\text{O}_9 + 3\text{FeO}$.

According to M. Messini, when ferrous sulphate is intravenously injected in the animal body, it forms **colloidal ferrous phosphate**. This colloid is prepared by mixing soln. of sodium phosphate and ferrous sulphate in presence of the colloid, and the time interval between mixing and the appearance of flocculation was noted. The protective action of gelatin is observable at a concentration of 2.5 grms. per litre and reaches a maximum at 12.5 grms. per litre, thereafter remaining constant. The smaller the concentration of ferrous phosphate the greater is its stability; the colloid remains stable for an indefinitely long period at a concentration of 0.006 grm. per litre and in presence of 12.5 grms. per litre of gelatin. Similar results were obtained with ox-blood serum as the protective colloid. The protective effect is observed at a concentration of 100 c.c. per litre, and the colloid seems to be permanently stable when the concentration of ferrous phosphate is 0.006 grm. per litre and that of serum 700 c.c. per litre.

N. S. Maskelyne and F. Field described a mineral from the Wheal Jane mine, Truro, Cornwall, and they called it **ludlamite**—after A. Ludlam. The analysis corresponds with **ferrous hydroxyphosphate**, $2\text{Fe}_3(\text{PO}_4)_2 \cdot \text{Fe}(\text{OH})_2 \cdot 8\text{H}_2\text{O}$. N. Fukuchi found it near Shimotsuke, Japan. The basic phosphates were discussed by P. Jolibois and L. Cloutier. According to N. S. Maskelyne and F. Field, it occurs in small, green, monoclinic crystals with the axial ratios $a : b : c = 2.2520 : 1 : 1.9819$,

and $\beta = 79^\circ 27'$. The crystals are tabular parallel to (001), and the (001)- and (111)-faces are striated or furrowed parallel to the (001)/(111)-edge. The (001)-cleavage is perfect, and the (100)-cleavage is distinct. The optic axial angles $2H_a = 97^\circ 50'$; $2H_0 = 119^\circ$; and $2V = 82^\circ 22'$; the optical character is positive; and the dispersion is small. The sp. gr. is 3.12; and the hardness 3 to 4. H. Buttgenbach gave for the mean birefringence, 0.0142. The basic phosphate is soluble in dil. hydrochloric and sulphuric acids. F. Müllbauer obtained a hydrated ferrous hydroxyphosphate, $\text{Fe}_7(\text{OH})_2(\text{PO}_4)_4 \cdot 5\text{H}_2\text{O}$, with small proportions of manganese and magnesium. The mineral occurs in apple-green, monoclinic crystals from Hagendorf, Bavaria. He called the mineral **lehnerite**—after F. Lehner. H. Steinmetz gave the formula: $\text{R}_3(\text{PO}_4)_2 \cdot 3\text{H}_2\text{O}$. The axial ratios are $a : b : c = 0.89651 : 1 : 2.4939$, and $\beta = 110^\circ 23'$. The basal cleavage is perfect. The mineral was discussed by H. Berman, and it is thought to be identical with ludlamite. E. S. Larsen thus compared some properties of the two minerals:

	Refractive indices			Opt. Char.	Axial Angle	Cleavage Perfect	Sp. gr.	Hardness
	α	β	γ					
Lehnerite	1.650	1.669	1.689	+	Large	(001)	3.19	3.5
Ludlamite	1.653	1.675	1.697	+	82°	(001)	3.12	3 to 4

A. Vogel, and J. W. Döbereiner observed that ferrous phosphate dissolves in aq. ammonia, forming a brown soln., which, on evaporation, gives up the ammonia. F. J. Otto prepared **ammonium ferrous phosphate**, $\text{NH}_4\text{FePO}_4 \cdot \text{H}_2\text{O}$, by mixing a soln. of iron in hot hydrochloric acid with a little ammonium sulphite, and then adding to the hot soln., a boiled aq. soln. of sodium hydrophosphate, when ferrous phosphate is precipitated. Aq. ammonia is then added in excess, and, after agitation, the flocculent precipitate is converted into tabular crystals which rapidly settle. If it be still flocculent, heat again and add more ammonia. The crystals are not now so sensitive to the oxidizing action of air, and they can be washed with thoroughly boiled water, and dried. No ammonia must be added, since its presence favours oxidation. The greenish-white, soft laminae are permanent in air, they are decomposed when heated, leaving at first ferrous phosphate, and this passes to the ferric phosphate. The salt gives off ammonia when treated with potash-lye, and if the mixture be boiled, ferrosic oxide is formed. The salt is insoluble in water, even when boiling. The freshly-prepared, moist salt is soluble even in dil. acids, but when it has been dried, it dissolves with difficulty even in conc. acids.

A. Sachs observed crusts of crystals lining cavities in the limonite mines of Zelesnyj Rog, near Anapa, on the Taman Peninsula, Kuban Province, Russia, and the mineral as a **calcium ferrous phosphate**, $2\text{CaO} \cdot \text{FeO} \cdot \text{P}_2\text{O}_5 \cdot 4\text{H}_2\text{O}$, or $(\text{Ca}, \text{Fe})_3(\text{PO}_4)_2 \cdot 4\text{H}_2\text{O}$. It was called **anapaite**. S. P. Popoff called it *tamanite*. Analyses were made by A. Sachs, S. P. Popoff, and J. Loczka. The crystals were examined by P. N. Tschirwinsky, and C. Palache. The greenish-white mineral has triclinic crystals with the axial ratios $a : b : c = 0.8757 : 1 : 0.5975$, and $\alpha = 132^\circ 22'$, $\beta = 106^\circ 47'$, and $\gamma = 83^\circ 28'$, according to A. Sachs; $0.7069 : 1 : 0.8778$, and $\alpha = 97^\circ 42'$, $\beta = 95^\circ 17'$, and $\gamma = 70^\circ 11'$, according to S. P. Popoff; and $0.8575 : 1 : 0.9401$, and $\alpha = 108^\circ 56' 40''$, $\beta = 104^\circ 05' 40''$, and $\gamma = 78^\circ 25' 24''$, according to C. Palache. The (100)-cleavage is perfect. The sp. gr. is 2.81 to 2.85, and the hardness 3.5.

S. G. Gordon obtained two minerals, **aluminium ferrous phosphates**, from the rhyolite at Llallagna, Oruro, in Bolivia. One called **vauxite**—after G. Vaux—has a composition corresponding with $4\text{FeO} \cdot 2\text{Al}_2\text{O}_3 \cdot 3\text{P}_2\text{O}_5 \cdot 24\text{H}_2\text{O} + 3\text{H}_2\text{O}$, where the $3\text{H}_2\text{O}$ is given off at 104° . Another specimen gave $\text{FeO} \cdot \text{Al}_2\text{O}_3 \cdot \text{P}_2\text{O}_5 \cdot 6\text{H}_2\text{O}$. The radiating aggregates of sky-blue, triclinic crystals have the axial ratios $a : b : c = 1.1510 : 1 : 1.2624$, and $\alpha = 99^\circ 21'$, $\beta = 102^\circ 14'$, and $\gamma = 110^\circ 14'$. The optical character is positive; the refractive indices, $\alpha = 1.551$, $\beta = 1.555$, and $\gamma = 1.562$; the hardness is 3.5; and the sp. gr. 2.375. The other mineral, called **paravauxite**, has

the composition: $5\text{FeO} \cdot 4\text{Al}_2\text{O}_3 \cdot 5\text{P}_2\text{O}_5 \cdot 26\text{H}_2\text{O} + 21\text{H}_2\text{O}$, where the $21\text{H}_2\text{O}$ is lost at 104° . Another specimen gave $\text{FeO} \cdot \text{Al}_2\text{O}_3 \cdot \text{P}_2\text{O}_5 \cdot 5\text{H}_2\text{O}$. The colourless, prismatic, triclinic crystals have the axial ratio $a : b : c = 0.5058 : 1 : 0.6882$, and $\alpha = 97^\circ 42'$, $\beta = 110^\circ 22'$, and $\gamma = 100^\circ 56'$. The (010)-cleavage is good; the optical character is positive; the refractive indices, $\alpha = 1.554$, $\beta = 1.558$, and $\gamma = 1.573$; the hardness is 3; and the sp. gr. 2.291. S. G. Gordon also obtained what he called **metavauxite**, in monoclinic crystals approximating $\text{FeO} \cdot \text{Al}_2\text{O}_3 \cdot \text{P}_2\text{O}_5 \cdot 4\text{H}_2\text{O}$. For **lazulite**, $(\text{Fe}, \text{Mg})\text{O} \cdot \text{Al}_2\text{O}_3 \cdot \text{P}_2\text{O}_5 \cdot \text{H}_2\text{O}$, *vide* 5. 33, 23.

For **ferrous lithium phosphate**, $\text{Li}_3\text{PO}_4 \cdot \text{Fe}_3(\text{PO}_4)_2$, *vide* manganese phosphates, *triphyllite*. F. Zambonini, and B. Gossner and H. Strunz studied the isogonism of triphyllite, LiFePO_4 , and olivine, MgMgSiO_4 ; for **manganous ferrous phosphate**, *vide* manganese phosphates, *triphite*. O. Barbosa described a mineral, manganous ferrous phosphate—**zwieselite**—from Sao Gonçalo, Rio de Janeiro. F. Müllbauer's hydrated manganese ferrous phosphate, $(\text{Mn}, \text{Fe}, \text{Mg})_3(\text{PO}_4)_2 \cdot 5\text{H}_2\text{O}$, or **wenzelite** was described in connection with manganous phosphates. The phosphorite **collinsite**, described by E. Poitevin, from François Lake, British Columbia, has the composition: $\text{Ca}_2(\text{Mg}, \text{Fe})(\text{PO}_4)_2 \cdot 2\frac{1}{2}\text{H}_2\text{O}$ —H. Steinmetz gave $\text{RHPO}_4 \cdot 2\text{H}_2\text{O}$ —sp. gr. 3.04; hardness 4.5; and indices of refraction $\alpha = 1.63$, $\beta = 1.626$, and $\gamma = 1.629$.

M. Websky reported a mineral to occur near Michelsdorf, Silesia, in irregular ellipsoids or distorted six-sided plates with a colour on a fresh surface varying from flesh-red to lavender-blue. It was called **sarcopsidite**, and it is a **ferrous manganous fluophosphate**, approximating $2\text{R}_3(\text{PO}_4)_2 \cdot \text{RF}_2$, where R denotes Fe, Mn, Mg, Ca. It was examined by E. F. Holden, and it is related in some respects to *triphite*, $(\text{Fe}, \text{Mn})\text{PO}_4 \cdot \{(\text{Fe}, \text{Mn})\text{F}\}$. This mineral was discussed by E. V. Shannon, and E. P. Henderson, who showed that the ferrous iron might range from 1.68 to 41.42 per cent. A variety rich in iron was called **zwieselite**. The sp. gr. of sarcopsidite is 3.64; and M. Websky gave 3.692 to 3.730; the hardness, 4; and, according to M. Websky, the refractive index is 1.700 to 1.725. The pleochroism is a yellow to yellowish-brown, and β light to dark olive-green. All water is expelled at 110° . It is soluble in dil. hydrochloric or sulphuric acid. D. Guimaraes described a phosphate of iron, manganese and other bases of the general formula: $4\text{R}_3'\text{PO}_4 \cdot 9\text{R}_3''(\text{PO}_4)_2$, and he called it **arrojadite**. The dark green, biaxial, monoclinic crystals have a perfect cleavage; they are pleochroic, having α and β colourless, and γ pale green; the optical character is negative; the optic axial angle $2V = 71^\circ$; the hardness is over 5; and the index of refraction $\gamma = 1.70$, and $\gamma - \alpha = 0.007$. It occurs at Serro Branco, Brazil, and is believed to be the same as a phosphate from South Dakota previously reported by W. P. Headden. H. Laubmann and H. Steinmetz reported a mineral, **phosphorphyllite**, to occur in colourless or pale blue, monoclinic crystals, with a perfect micaceous cleavage, at Hagendorf, Bavaria. It is a hydrated **ferrous aluminium sulphatophosphate** approximating $3(\text{Fe}, \text{Mg}, \text{Ca}, \text{K})_3(\text{PO}_4)_2 \cdot 2\text{Al}(\text{OH})\text{SO}_4 \cdot 9\text{H}_2\text{O}$. It was also discussed by C. Palache and H. Berman. H. Steinmetz, and H. Laubmann and H. Steinmetz described a ferrous manganous phosphate, $(\text{Fe}, \text{Mn})_3(\text{PO}_4)_2 \cdot 3\text{H}_2\text{O}$, occurring as cloudy white or green crystalline masses in the pegmatite at Hagendorf, Bavaria, and it was called **phosphoferrite**. The rhombic crystals have the axial ratios $a : b : c = 0.8629 : 1 : 0.9418$, and sp. gr. 2.96 to 3.10. The (010)-cleavage is not perfect; the optical character is negative.

H. St. C. Deville and H. Caron reported the preparation of **manganous ferrous fluophosphate**, $(\text{Mn}, \text{Fe})_3(\text{PO}_4)_2 \cdot (\text{Mn}, \text{Fe})\text{F}_2$, as well as of **manganous ferrous chlorophosphate**, $(\text{Mn}, \text{Fe})_3(\text{PO}_4)_2 \cdot (\text{Mn}, \text{Fe})\text{Cl}_2$.

According to H. Berman and F. A. Gonyer the yellowish-green, tabular crystals of **dickinsonite** have the composition: $7(\text{Mn}, \text{Fe})\text{O} \cdot 0.2(\text{K}_2, \text{Na}_2, \text{Ca})\text{O} \cdot 3\text{P}_2\text{O}_5 \cdot \text{H}_2\text{O}$; *fairfieldite* has the composition: $(\text{Mn}, \text{Fe})\text{O} \cdot 0.2\text{CaO} \cdot \text{P}_2\text{O}_5 \cdot 2\text{H}_2\text{O}$; *reddingite*, $3(\text{Mn}, \text{Fe})\text{O} \cdot \text{P}_2\text{O}_5 \cdot 3\text{H}_2\text{O}$; *triploidite*, $4(\text{Mn}, \text{Fe})\text{O} \cdot \text{P}_2\text{O}_5 \cdot \text{H}_2\text{O}$; and *lithiophilite*, $2(\text{Mn}, \text{Fe})\text{O} \cdot \text{Li}_2\text{O} \cdot \text{P}_2\text{O}_5$ —*vide* manganese phosphates, 12. 64, 26. A. Breithaupt described a clove-brown variety of triploidite, rich in iron, as the mineral **zwieselite**,

and E. F. Glocker, as the mineral *zwieselite*. It occurs at Rabenstein, in Bavaria; and O. Barbosa described a variety from São Gonçalo, Brazil.

A. Lévy reported a yellowish-white, pale yellowish-brown, or brownish-black, crystalline mineral occurring in Cornwall and Devon. Its composition corresponds with **ferrous aluminium phosphate**, $2\text{AlPO}_4 \cdot 2(\text{Fe}, \text{Mn})(\text{OH})_2 \cdot 2\text{H}_2\text{O}$, and he called it **childrenite**—after J. G. Children. Another mineral with a higher proportion of manganese, occurring in Hebron, U.S.A., was described by G. J. Brush and E. S. Dana, and named **eosphorite**—*vide* 12. 64, 26. According to A. Lévy, and J. P. Cooke, childrenite appears in six-sided pyramids belonging to the rhombic system. W. H. Miller gave for the axial ratios $a : b : c = 0.77801 : 1 : 0.52575$; and A. des Cloizeaux gave for the optic axial angles $2E = 75^\circ 22'$ for red-light, $74^\circ 25'$ for yellow-light, and $71^\circ 31'$ for blue-light. The cleavage (100) is imperfect; the optical character is negative; the sp. gr. is 3.18 to 3.24; and the hardness 4.5 to 5.0. Observations were made by F. Slavik, and F. Kolbeck. E. S. Larsen gave for the indices of refraction $\alpha = 1.643$, $\beta = 1.678$, and $\gamma = 1.684$. Childrenite is soluble in hydrochloric acid. F. Slavik described a mineral from Ehrenfriedersdorf which he called **roscherite**—after W. Roscher. The mineral occurs in short columns or thin plates which are pleochroic, α yellow with a tinge of olive-green, β brownish-yellow with a tinge of green, and γ chestnut-brown. Its composition corresponds with $(\text{Fe}, \text{Mn}, \text{Ca})_2\text{Al}(\text{OH})(\text{PO}_4)_2 \cdot 2\text{H}_2\text{O}$. The monoclinic crystals have the axial ratios $a : b : c = 0.94 : 1 : 0.88$, and $\beta = 99^\circ 50'$. The (001)-cleavage is nearly perfect, and the (010)-cleavage is distinct. The mean index of refraction is 1.625 to 1.630. The sp. gr. is 2.916, and the hardness 4.5.

C. W. Scheele found that phosphoric acid dissolves iron with the evolution of hydrogen, and the formation first of an acidic salt, and afterwards a greenish-white substance approaching the normal salt in composition. A. Vogel observed that the acid soln. gives a greenish precipitate with ammonia, and it is soluble in an excess of that reagent. H. Debray prepared **ferrous hydrophosphate**, $\text{FeHPO}_4 \cdot \text{H}_2\text{O}$, by dissolving iron in a boiling soln. of phosphoric acid; or by boiling a soln. of ferrous sulphate with magnesium phosphate prepared in the cold. The salt was also prepared by A. C. Becquerel. E. Erlenmeyer regarded it as impure orthophosphate, and the conditions of stability were worked out by S. R. Carter and N. H. Hartshorne, Fig. 690. The salt $2\text{FeO} \cdot \text{P}_2\text{O}_5 \cdot 5\text{H}_2\text{O}$ can be regarded as the *dihydrate*, $\text{FeHPO}_4 \cdot 2\text{H}_2\text{O}$, and the salt $2\text{FeO} \cdot \text{P}_2\text{O}_5 \cdot 3\text{H}_2\text{O}$ becomes the *monohydrate*, $\text{FeHPO}_4 \cdot \text{H}_2\text{O}$. The dotted line for the monohydrate with concentrations between 9.2 and 11.9 per cent. FeO, and 24.29 to 36.99 per cent. P_2O_5 , refer to the amorphous salt. The crystalline salt appears with concentrations 7.71 to 11.29 per cent. FeO, and 21.6 to 37.21 per cent. P_2O_5 . H. Debray observed that the dihydrate crystallizes in colourless needles which become blue on exposure to air. S. R. Carter and N. H. Hartshorne said that the crystals are biaxial, and positive, with an optic axial angle $2V = 60^\circ$ to 70° . H. Debray said that the salt is insoluble in water. Water at 250° converts the salt into vivianite. The salt is readily soluble in dil. acids, and in aq. ammonia. W. Manchot found that a viscid liquid is produced when a soln. of ammonium phosphate is added to alcohol saturated with nitric oxide at 0° ; the oil crystallizes when placed in a freezing mixture, and when purified by re-crystallization at a low temp., brown, flaky crystals of **ferrous nitrosyl hydrophosphate**, $\text{FeHPO}_4 \cdot \text{NO}$, melting at 16° , are formed. On exposure to air, it yields white ferric phosphate. The nitrosyl complex was also studied by I. Bellucci, and E. W. Merry. R. Weinland and co-workers also prepared complexes with pyridine and methyl alcohol, $\text{FeHPO}_4 \cdot 4\text{C}_5\text{H}_5\text{N} \cdot 2\text{CH}_3\text{OH} \cdot 4\text{H}_2\text{O}$, and $\text{FePO}_4 \cdot \text{FeHPO}_4 \cdot 4\text{C}_5\text{H}_5\text{N} \cdot 4\text{CH}_3\text{OH} \cdot 8\text{H}_2\text{O}$. H. Debray prepared crystals of **ammonium ferrous hydrophosphate**, $(\text{NH}_4)_2\text{Fe}(\text{HPO}_4)_2 \cdot 4\text{H}_2\text{O}$, by digesting the normal salt for 7 or 8 days with a conc., acid soln. of ammonium phosphate.

E. Erlenmeyer prepared **ferrous dihydrophosphate**, $\text{Fe}(\text{H}_2\text{PO}_4)_2 \cdot 2\text{H}_2\text{O}$, by dissolving iron in an excess of phosphoric acid in a current of hydrogen to protect it

from air. The excess of acid is removed by washing with ether, and the product is dried in hydrogen. The salt is a white, crystalline powder, which readily oxidizes in air, forming a ferric salt. It is readily soluble in water, but is insoluble in alcohol. The salt is the $\text{FeO} \cdot \text{P}_2\text{O}_5 \cdot 4\text{H}_2\text{O}$ observed by S. R. Carter and N. H. Hartshorne, and the conditions of equilibrium at 70° are summarized in Fig. 690.

A. Schwarzenberg prepared **ferrous pyrophosphate**, $\text{Fe}_2\text{P}_2\text{O}_7$, as an unstable, white powder by the double decomposition of ferrous sulphate, and sodium pyrophosphate; or by heating ferrous orthophosphate; or by reducing ferric phosphate with hydrogen. On exposure to air, the salt turns green, and ultimately brown. The salt was also prepared by L. Ferrand. H. Struve obtained the pyrophosphate by heating the normal salt in hydrogen. H. Rose, and G. Buchner noted that the precipitate is soluble in an excess of the precipitant. J. H. Gladstone found that when the soln. in dil. sulphuric acid is boiled, it deposits a precipitate of ferric pyrophosphate. C. V. Smythe found that non-ionized ferrous pyrophosphate or metaphosphate is rapidly oxidized by air regardless of the acidity of the soln., whereas ferrous sulphate in similarly acidified soln. suffered no appreciable oxidation. P. Pascal observed that a sat. soln. of ferrous pyrophosphate in one of sodium pyrophosphate slowly deposits crystals of **sodium ferrous pyrophosphate**, $\text{Na}_3\text{Fe}_2(\text{P}_2\text{O}_7)_3$. Solutions containing alkali ferrous pyrophosphate reduce soln. of silver and gold salts in the cold, but platinum salts are not reduced even on boiling. In the case of dil. soln., the reduced gold and silver are colloidal, and strongly coloured. Mercuric salts are reduced to mercurous salts and then to mercury; with dil. soln., the mercury is colloidal and maroon by transmitted and grey by reflected light. Soln. of cupric salts furnish colloidal cuprous hydroxide, yellow by transmitted and green by reflected light. The yellow colour becomes darker in time, owing to the reduction of the hydroxide to metallic copper. At 100° , the copper is deposited on glass as a thin film. S. Freed and C. Kasper discussed the complex ion $[\text{Fe}_2(\text{P}_2\text{O}_7)_3]^{++++}$. J. Persoz obtained a soln. of the salt and noted that it is coloured brown by hydrogen sulphide, and is completely precipitated by ammonium sulphide. H. A. Spoehr studied the catalytic action of the salt in the oxidation of carbohydrates, and J. H. C. Smith and H. A. Spoehr, in the oxidation of soln. of potassium arsenite, and sodium sulphite. A. Rosenheim prepared **ammonium ferrous pyrophosphate**, $(\text{NH}_4)_3[\text{Fe}(\text{OH})\text{P}_2\text{O}_7] \cdot 2\text{H}_2\text{O}$.

A. Colani prepared **ferrous metaphosphate**, $\text{Fe}(\text{PO}_3)_2$, as a white, insoluble powder by the action of fused metaphosphoric acid on metallic iron, on ferrous chloride or oxalate, or, best of all, ferrous phosphate, in a gold crucible in an atm. of carbon dioxide. The product is insoluble in hydrochloric and nitric acids, but it is attacked by hot, conc. sulphuric acid—for the oxidation of the soln., *vide supra*. A. Glatzel reported a *tetrahydrate*. C. G. Lindbom prepared **ferrous trimetaphosphate**, $\text{Fe}_3(\text{P}_3\text{O}_9)_2$, by double decomposition with the barium salt and ferrous sulphate. The salt is slightly soluble in cold water, more easily soluble in hot water; and after ignition it is soluble in hydrochloric acid only after a prolonged boiling. A. Glatzel prepared **ferrous tetrametaphosphate**, $\text{Fe}_2\text{P}_4\text{O}_{12} \cdot 10\text{H}_2\text{O}$, by heating an excess of phosphoric acid with a ferrous salt or oxide so that a molten mass is obtained; and this is slowly cooled. H. Lüdert obtained gelatinous **ferrous hexametaphosphate**, $\text{Fe}_3(\text{PO}_3)_6$, by double decomposition between sodium hexametaphosphate and ferrous salts. These two salts may be the same chemical individuals. P. Pascal prepared **sodium ferrous metaphosphate**, $\text{Na}_4\text{Fe}(\text{PO}_3)_6$, by the method used for the pyrophosphate.

M. Strange prepared **sodium ferrous triphosphate**, $\text{Na}_3\text{FeP}_3\text{O}_{10} \cdot 11\frac{1}{2}\text{H}_2\text{O}$, by adding sodium triphosphate to a soln. of ferrous sulphate. The soln., after filtration deposits the salt in slender, silky, white needles. It is stable when dry, but in contact with water, it rapidly oxidizes and forms a brown syrup which is thought to be a basic salt. It dissolves in nitric acid, and, on warming, is converted into ferric pyrophosphate with a violent evolution of nitric oxide. It is dehydrated

only by heating to the m.p., and ferrous oxide is then deposited. Observations were made by P. Glühmann.

H. Laubmann and H. Steinmetz reported an acid ferrous phosphate, $4\cdot5(\text{Fe}, \text{Mg}, \text{Ca})\cdot 3\text{PO}_4\cdot \text{H}_2\text{PO}_4$, or $\text{H}_6\text{R}_3''(\text{PO}_4)_6$, in the pegmatite at Hagendorf, Bavaria. It was called **phosphoferrite**.

J. J. Berzelius, C. F. Rammelsberg, G. Jenzsch, and G. C. Wittstein reported a **ferrosic phosphate** of indefinite composition to be formed during the oxidation of vivianite, or of artificial ferrous phosphate in air; and W. N. Ipatéeff and W. Nikolajeff observed that the crystals of the alleged ferrosic phosphate are green, blue, or black, according to the proportion of contained ferrous iron; and that under water, at an elevated temp. and with hydrogen under press., the ferric phosphate is partially reduced to ferrosic phosphate.

§ 51. The Ferric Phosphates

The hydrated normal **ferric phosphates** have been reported in nature. A. Nies¹ described a mineral from Dünsberg, Giessen, etc., which he named **strengite**—after A. Streng. Analyses reported by A. Nies, and G. A. König correspond with the *dihydrate*, $\text{FePO}_4 \cdot 2\text{H}_2\text{O}$. A. Lacroix described a mineral, which he called *vilateite*, which is thought to be a manganiferous strengite. The colour of strengite is peach-blossom-red, carmine and other shades of red, and sometimes it is nearly colourless. The streak is yellowish-white. It generally occurs in globular and botryoidal forms, or aggregates with a radiated, fibrous structure, and a drusy surface. Good crystals are rare. W. Bruhns and K. Busz gave for the axial ratios of the rhombic crystals, $a : b : c = 0.86517 : 1 : 0.98272$. The (100)-cleavage is imperfect. The optic axial angle is nearly 60° . W. T. Schaller gave $\mu_\alpha = 1.71$, $\mu_\gamma = 1.735$, and for the double refraction $\mu_\gamma - \mu_\alpha = 0.025$. E. S. Larsen found samples with $\mu_\alpha = 1.697$ to 1.730 ; $\mu_\beta = 1.708$ to 1.732 ; and $\mu_\gamma = 1.722$ to 1.762 ; and the pleochroism, α pale violet, β violet, and γ deep blue. According to A. Nies, and A. Lacroix, the sp. gr. is 2.87; and the hardness 3 to 4. It is said to be insoluble in nitric acid, and easily soluble in hot hydrochloric acid. W. Knaust studied the coagulation of colloidal soln. of ferric hydroxide peptized with phosphoric acid.

W. Bruhns and K. Busz described a mineral from Eiserfeld, Siegen, and they called it **phosphosiderite**. The analysis corresponds with the *tetrithaheptahydrate*, $\text{FePO}_4 \cdot 1\frac{3}{4}\text{H}_2\text{O}$. H. Laubmann and H. Steinmetz observed that the mineral occurs at Kreuzberg. According to W. Bruhns and K. Busz, the colour of phosphosiderite is peach-blossom-red, or reddish-violet. It occurs in prismatic crystals belonging to the rhombic system, and having the axial ratios $a : b : c = 0.53302 : 1 : 0.87723$. The pleochroism of the crystals is distinct, since α is a pale rose, β is carmine-red, and γ colourless. The (010)-cleavage is perfect. The optic axial angle is large; $2K = 62^\circ 55'$; $2E = 126^\circ 26'$; $2V = 63^\circ 4'$ for yellow-light. The optical character is negative, and the index of refraction $\beta = 1.7315$ for yellow-light. The sp. gr. is 2.76; and the hardness 3.75. It is nearly insoluble in nitric acid, but completely soluble in hydrochloric acid. It is possible by using a different orientation of the crystals to obtain the ratios $a : b : c = 0.82285 : 1 : 0.93805$, which is not far from strengite, but the two minerals differ in optical orientation, and chemically.

G. Cesaro described yellow, spherical aggregates of radiating needles which he called **koninckite**—after L. G. de Koninck. The mineral occurs at Richelle, Belgium. The analysis corresponds with the *trihydrate*, $\text{FePO}_4 \cdot 3\text{H}_2\text{O}$. The cleavage is transverse; the optical extinction parallel; the optical character positive; the optic axial angle is small; and the dispersion $\gamma - \alpha = 0.012$, and $\beta - \alpha = 0.002$. E. S. Larsen gave for the index of refraction $\alpha = 1.645$, and $\gamma = 1.656$. The sp. gr. is 2.3; and the hardness 3.5.

T. Bergman observed that when a soln. of ferric chloride is treated with sodium hydrophosphate, amorphous, yellowish-white ferric phosphate, $\text{FePO}_4 \cdot n\text{H}_2\text{O}$, is precipitated. E. Heydenreich obtained the precipitation, in a similar way, from soln. of ferric chloride or sulphate. H. Debray obtained it by exposing to air a soln. of iron in phosphoric acid; C. von Girsewald and H. Weidmann, by roasting ferrophosphorus; E. Erlenmeyer, by saturating with iron a 48 per cent. soln. of phosphoric acid, heated on a water-bath; R. F. Weinland and F. Ensgraber, by heating on the water-bath a mixture of ferric chloride or acetate with phosphoric acid or primary potassium phosphate; and G. Arth, by evaporating a mixed soln. of 4 mols of ferric chloride and 1 mol of sodium hydrophosphate with an excess of nitric acid—as the liquid becomes syrupy, there is a copious separation of ferric phosphate. According to F. L. Winckler, E. Heydenreich, and H. Struve, the salt precipitated from neutral soln. approximates $\text{Fe}_2\text{O}_3 \cdot \text{P}_2\text{O}_5 \cdot n\text{H}_2\text{O}$, and, according to H. W. F. Wackenroder and C. Ludwig, and C. F. Mohr, the same substance is precipitated from an acetic acid soln., while C. R. Fresenius and H. Will said that in the presence of acetic acid, the precipitate is $2\text{Fe}_2\text{O}_3 \cdot 3\text{P}_2\text{O}_5 \cdot n\text{H}_2\text{O}$. R. M. Caven

recommended adding the soln. of ferric chloride to one of orthophosphoric acid prepared by boiling glacial metaphosphoric acid with water until it no longer gives a precipitate with barium chloride. The phosphoric acid, calculated as H_3PO_4 , should be double the theoretical amount required to precipitate the iron. The precipitate so obtained, when suspended in water, appears perfectly white, and when strained off on calico it appears bluish-white. The washing should be done with cold water, on account of the rapid hydrolysis with hot water. F. K. Cameron and L. A. Hurst observed that it is very difficult to prepare normal ferric phosphate by the precipitation process, because, as emphasized by B. Lachowicz, the precipitate loses phosphoric acid continuously when washed by water: $\text{FePO}_4 + 3\text{H}_2\text{O} \rightleftharpoons \text{Fe}(\text{OH})_3 + \text{H}_3\text{PO}_4$. The product, in consequence, contains too much or too little phosphoric acid, unless, by chance, the excess originally provided for has just been removed. This continuous hydrolysis also explains how many basic phosphates occur in nature, or have been prepared artificially. F. K. Cameron and L. A. Hurst observed no evidence of the formation of a definite basic salt. F. K. Cameron and J. M. Bell investigated the system with between 0.942 and 4.706 per cent. P_2O_5 at 25° , and the results are in accord with the assumption that there is a continuous change in the composition of the solid phase, say $\text{Fe}_2\text{O}_3 \cdot \text{P}_2\text{O}_5 \cdot n\text{H}_2\text{O}$, due to the adsorption of phosphoric acid. E. Erlenmeyer obtained three well-defined phosphates: $\text{Fe}_2\text{O}_3 \cdot \text{P}_2\text{O}_5 \cdot 4\text{H}_2\text{O}$; $\text{Fe}_2\text{O}_3 \cdot 2\text{P}_2\text{O}_5 \cdot 8\text{H}_2\text{O}$; and $\text{Fe}_2\text{O}_3 \cdot 3\text{P}_2\text{O}_5 \cdot 6\text{H}_2\text{O}$, as well as a series of ill-defined amorphous products with the ratio $\text{Fe}_2\text{O}_3 : \text{P}_2\text{O}_5$ ranging from 8 : 9 to 8 : 11, and the evidence agrees with the assumption that the products are stages in a continuous process of adsorption. R. F. Weinland and F. Ensgraber observed a marked difference between the normal phosphate prepared as just indicated, and the products obtained by precipitating soln. of ferric salt with alkali phosphate soln. in the cold. The amorphous products in the latter case always varied in composition, and they contained more acid than is required for the normal salt. The subject was studied by L. Cloutier.

W. R. G. Atkins studied the effect of the acidity of the soln. on the composition of the phosphate; and S. R. Carter and N. H. Hartshorne made a partial study of

FIGS. 691 and 692.—Equilibrium Studies of the System: $\text{Fe}_2\text{O}_3\text{--P}_2\text{O}_5\text{--H}_2\text{O}$, at 25° and 70° .

the ternary system: $\text{Fe}_2\text{O}_3\text{--P}_2\text{O}_5\text{--H}_2\text{O}$, at 25° and at 70° . The results are summarized in Figs. 691 and 692. Expressing concentrations in percentage, they found:

Fe_2O_3	.	.	.	trace	0.23	1.40	2.43	4.42
P_2O_5	.	.	.	5.93	10.1	14.1	19.8	21.7
					$\underbrace{\hspace{10em}}_{\text{FePO}_4 \cdot 2\frac{1}{2}\text{H}_2\text{O}}$			

The solid phase with the first mixture is $\text{FePO}_4 \cdot n\text{H}_2\text{O} + \text{H}_3\text{PO}_4$. This means that at 25° , and the lowest acid concentration, an amorphous compound, $\text{Fe}_2\text{O}_3 \cdot \text{P}_2\text{O}_5 \cdot n\text{H}_2\text{O}$,

is stable, and it adsorbs phosphoric acid from the mother-liquor; at higher acid concentrations another amorphous, but granular phase appears, namely, the *hemipentahydrate*, $\text{Fe}_2\text{O}_3 \cdot \text{P}_2\text{O}_5 \cdot 5\text{H}_2\text{O}$, or $\text{FePO}_4 \cdot 2\frac{1}{2}\text{H}_2\text{O}$. G. W. Waine's results agree with this. This product does not adsorb phosphoric acid. B. Ricca and P. Meduri studied the system.

Analyses of ferric phosphates were made by B. Lachowicz, P. Jolibois and L. Cloutier, M. von Wrangell and E. Koch, and F. K. Cameron and L. A. Hurst. G. C. Wittstein observed that the precipitate dried at 50° has the composition: $\text{Fe}_2\text{O}_3 \cdot \text{P}_2\text{O}_5 \cdot 8\text{H}_2\text{O}$; and when it is dried at 100° , C. F. Rammelsberg, A. Millot, and H. Debray found $\text{Fe}_2\text{O}_3 \cdot \text{P}_2\text{O}_5 \cdot 4\text{H}_2\text{O}$. The product obtained by E. Erlenmeyer was represented as a *dihydrate*, $\text{FePO}_4 \cdot 2\text{H}_2\text{O}$, like strengite, but the analyses correspond with about $2\frac{1}{4}\text{H}_2\text{O}$. A. de Schulten also observed that the dihydrate is formed when 26 c.c. of a soln. of hydrated ferric chloride in half its weight of water, is heated with 4 to 5 c.c. of a soln. of phosphoric acid, of sp. gr. 1.578, in sealed tubes at 180° to 190° , for several hours; microscopic, rose-coloured crystals are obtained, which are insoluble in nitric acid, but dissolve in hydrochloric acid. If a smaller quantity of phosphoric acid is used, the crystals are much smaller; whilst if the acid is in excess, the yield is much smaller, or the liquid remains perfectly clear. In the latter case, if the proportion of phosphoric acid is not very large, crystals are still obtained by heating the tube to a higher temperature, which, however, must not exceed 210° , or a green basic phosphate is formed. When ferric hydroxide is heated with a soln. of phosphoric acid in sealed tubes, the product is amorphous. Unlike strengite, these crystals are monoclinic, those of strengite are rhombic. The sp. gr. is 2.74 at 15° ; and the crystals are birefractive, and frequently twinned. In some directions, the twins yield sections closely resembling those of rhombic strengite. R. F. Weinland and F. Ensgraber regarded their product as the hemipentahydrate. S. R. Carter and N. H. Hartshorne's results at 70° are summarized in Fig. 692, and expressing concentrations in percentages, they found that the solid phase with the first mixture is $\text{FePO}_4 \cdot n\text{H}_2\text{O} + \text{H}_3\text{PO}_4$; and thereafter four solid phases appear:

Fe_2O_3	trace	< 0.1	5.45	7.12	8.10	9.79	85.8	5.28	3.46
P_2O_5	4.07	6.38	37.43	43.92	52.32	53.20	55.84	58.07	60.47
			$\text{FePO}_4 \cdot 2\frac{1}{4}\text{H}_2\text{O}$	$\text{Fe}_2\text{O}_3 \cdot 2\text{P}_2\text{O}_5 \cdot 8\text{H}_2\text{O}$	$\text{Fe}_2\text{O}_3 \cdot 3\text{P}_2\text{O}_5 \cdot 10\text{H}_2\text{O}$	$\text{Fe}_2\text{O}_3 \cdot 3\text{P}_2\text{O}_5 \cdot 6\text{H}_2\text{O}$			

Accepting the analysis of the minerals strengite, phosphosiderite, and koninckite there appears to be an unknown hydrate, as well as the tri-, hemipenta-, di-, and tetraheptahydrates. R. F. Weinland and F. Ensgraber found that the water mols. of the hemipentahydrate are strongly bound. No water is lost in vacuo over sulphuric acid. The evolution of water begins at 110° , it comes off faster at 120° , and at about 175° , nine-tenths is lost; the remainder is expelled at 210° . They regard this phosphate as the ferric salt of a **hydrodiphosphatoferric acid**, $\text{H}_3[\text{Fe}(\text{PO}_4)_2]$, namely, $\text{Fe}[\text{Fe}(\text{PO}_4)_2] \cdot 5\text{H}_2\text{O}$, corresponding with a series of salts which they prepared—*vide infra*. A. Bailer's results at 40° are summarized in Fig. 693. He obtained the *tetrahydrate*, $\text{H}_3[\text{Fe}(\text{PO}_4)_2] \cdot 4\text{H}_2\text{O}$, and the *hemipenta-hydrate*, $\text{H}_3[\text{Fe}(\text{PO}_4)_2] \cdot 2\frac{1}{2}\text{H}_2\text{O}$, as well as **hydrotriposphatoferric acid**, $\text{H}_6[\text{Fe}(\text{PO}_4)_3]$; and the *dihydrate*, $\text{H}_6[\text{Fe}(\text{PO}_4)_3] \cdot 2\text{H}_2\text{O}$, as well as **hydrotetraphosphatoferric acid**, $\text{H}_9[\text{Fe}(\text{PO}_4)_4]$. Observations were made by A. Sanfourche and B. Focet on the complex:

FIG. 693.—The Ternary System : $\text{FePO}_4\text{--H}_3\text{PO}_4\text{--H}_2\text{O}$.

$\text{Ca}[\text{H}_2\text{Fe}(\text{PO}_4)_2]_2$. The subject was studied by L. Dede, who found that the conductivity curves of soln of ferric chloride and phosphoric acid in equivalent proportions gave indication of the existence of **hydrotrichloroferriphosphoric acid**, $\text{H}_3[\text{Cl}_3\text{Fe}(\text{PO}_4)]$, which could not be isolated, and also with more dil. soln. of $\text{H}_3[\text{Fe}(\text{PO}_4)_2] \cdot 2.5\text{H}_2\text{O}$.

E. Angelescu and G. Balanescu observed that well-defined ferric phosphates can be obtained only in acidic soln. According to E. A. Schneider, **colloidal ferric phosphate** is produced when a soln. of ferric chloride, saturated with normal calcium phosphate, is dialyzed. When the diffusate contained no more chloride, the ferric phosphate sol set to a jelly. The hydrogel forms a reddish-brown soln. with aq. ammonia, and ammonium phosphate is removed on dialysis. It was also prepared by E. Grimaux, and H. N. Holmes and co-workers. W. J. Sell observed that in the presence of ammonia, a soln. of ammonium hydrophosphate dissolves ferric phosphate, forming a brownish-red soln. If the soln. is dialyzed until all the electrolytes are removed, a slightly basic ferric phosphate sol is formed. The colloidal soln. of ferric phosphate is tasteless and without action on litmus. The addition of alkali chlorides and most other salts induces gelatinization. The very small value of the conductivity points to there being no free ions in the solution, and this is confirmed by the failure of potassium thiocyanate and ferrocyanide to give any colour reaction; these reagents cause gelatinization only. On the other hand, hydrogen sulphide and ammonium sulphide both give black precipitates. H. N. Holmes and R. E. Rindfus observed the peptization of ferric phosphates by an aq. soln. of methylamine, aq. ammonia, ferric chloride, or sulphate, and nitric or hydrochloric acid. N. R. Dhar and S. Ghosh, and S. Ghosh and S. Prakash studied the subject; and A. C. Chatterji and N. R. Dhar, the rhythmic precipitation of the hydrogel. H. P. Varma and S. Prakash, and S. Prakash and N. R. Dhar found that a soln. of 0.5M- FeCl_3 , and half its vol. of 22 per cent. potassium dihydrophosphate soln. when dialyzed form a clear, red soln. S. Ghosh and co-workers studied the coagulation of the hydrosol by potassium sulphate, and by heat. The viscosities of 1.5 c.c. of the soln. with 46 grms. of ferric phosphate per litre and 1.2 c.c. of 0.25N- K_2SO_4 , at 30°, were:

Age . . .	0	40	80	130	185	252 mins.
Viscosity .	0.01859	0.02159	0.02648	0.03176	0.03876	0.04997

S. N. Banerji and S. Ghosh studied the viscosities of the sol at varying pressures. According to A. Arzruni, ferric phosphate is dimorphous; as just indicated, strengite is rhombic, and the artificial salt is monoclinic. The sp. gr. of the artificial dihydrate, given by A. de Schulten, is 2.74 at 15°. The action of heat on the hydrate has been indicated above. M. Faraday said that ferric phosphate is magnetic, and L. A. Welo found that the sp. magnetic susceptibility is 71.40×10^{-6} mass unit. L. N. Bhargava and S. Prakash studied the magnetic properties.

C. Freese observed that when ferric phosphate is heated to redness in hydrogen, ferric pyrophosphate is formed; but, according to H. Struve, if the temp. is high enough, iron phosphide, Fe_4P_3 , is produced. W. Ipatéeff and W. Nikolaieff found that hydrogen above 150°, and under press., has no appreciable action on phosphoric acid and its alkali salts, but ferric phosphate under water, is partially reduced, yielding a continuous series of complex ferrosic phosphates of the type: $\text{Fe}_n''' \text{Fe}_m' \text{PO}_4 \cdot x\text{H}_2\text{O}$ —resembling the vivianites. T. Bergman said that 1 part of the precipitated salt is soluble in 1500 parts of boiling water, but insoluble in cold water. According to B. Lachowicz, the precipitated phosphate is only very sparingly soluble in water; but it is rapidly decomposed by contact with that liquid. The quantity hydrolyzed: $\text{FePO}_4 + 3\text{H}_2\text{O} \rightleftharpoons \text{Fe}(\text{OH})_3 + \text{H}_3\text{PO}_4$, at any particular temp., depends on the amount of water present, and the decomposition does not proceed beyond a fixed limit, unless the phosphoric acid which has entered into soln. is removed from the sphere of action. In the presence of a large excess of water, the whole of the phosphoric acid is eventually drawn from

the iron phosphate. F. K. Cameron and L. A. Hurst confirmed these conclusions. They found that with a slightly acidic phosphate, after 43 days' agitation at 25°, and varying proportions of water :

Water	25	60	85	140	200	800 c.c. per gram
Dissolved PO_4	0.302	0.257	0.136	0.099	0.080	0.029 grm. per litre

The phosphoric acid was still going into soln. at the end of the 43 days. The greater the proportion of water in contact with the ferric phosphate, the less is the concentration of the soln. with respect to phosphoric acid, although the total amount passing into soln. increased with increasing proportions of water. The greater the proportion of water, the less relatively is the decomposition, although actually the amount of decomposition was greater. Analogous results were obtained with a slightly basic phosphate. C. F. Mohr, and W. Hess observed that in washing the phosphate for analysis, hot water extracts phosphoric acid. Observations on the hydrolysis were also made by R. M. Caven, F. K. Cameron and L. A. Hurst, and M. von Wrangell and E. Koch; and on the gel formation, by H. L. Dube.

The presence of saline substances in water modifies its action on ferric phosphate. E. Heiden reported that the presence of sodium, potassium, and ammonium salts increases the solubility of ferric phosphate, but later work shows that this is not always the case. B. Lachowicz observed that one class of salts promotes the hydrolysis, another class retards it, whilst a third class has no action. Soln. of salts having an alkaline reaction hydrolyze the salt the more rapidly; whilst soln. of neutral salts have very little influence on the rate of hydrolysis. F. K. Cameron and L. A. Hurst found that, at 25°, with 20 c.c. of a soln. of sodium nitrate containing :

NaNO_3	0	5.0	25	75	150	300 grms. per litre
Dissolved PO_4	0.3500	0.2237	0.1912	0.1622	0.1451	0.1084 grm. per litre

per gram of ferric phosphate during 40 days' action; with soln. of potassium chloride :

KCl	0	0.111	5.0	25	150	300 grms. per litre
Dissolved PO_4	0.3500	0.2256	0.1127	0.0905	0.0871	0.0871 grm. per litre

and with potassium sulphate during 19 days' action :

K_2SO_4	3	6	25	50	75	150 grms. per litre
Dissolved PO_4	0.320	0.344	0.366	0.372	0.367	0.364 grm. per litre

These results obtained with a slightly acidic phosphate are similar to those obtained with a slightly basic phosphate. In these cases, the quantity of phosphoric acid in the soln. falls off rapidly as the conc. of the neutral salt is increased, or else, as in the case of the potassium sulphate soln., the phosphoric acid content increases slightly with increasing quantities of potassium sulphate in soln. The acidity increases markedly as the conc. of the neutral salt increases, and the effect is probably due to a selective adsorption whereby the basic part unites with the solid residue, leaving free acid in soln. B. Lachowicz found the following proportions of ferric oxide and phosphoric acid were dissolved from ferric phosphate by soln. of salts of this kind, during 24 hrs'. action, at 21° to 26°, using 0.5864 grm. of ferric phosphate, and a litre of soln. :

Grams	H_2O	Na_2SO_4	$(\text{NH}_4)_2\text{SO}_4$	KCl	NaCl	NH_4Cl	NaNO_3
P_2O_5 (dissolved)	—	6.761	6.364	5.624	4.410	4.029	6.464 per litre
Fe_2O_3 (dissolved)	6.6	8.1	6.2	5.6	5.8	4.8	4.5 mgrms. per litre
	2.6	1.5	2.1	2.0	2.2	3.2	2.5 „ „

The action with these soln. is very little different from that of water alone; but H. Rose observed that a soln. of sodium carbonate changes the colour of ferric phosphate to reddish-brown, and phosphoric acid is dissolved. J. J. Berzelius

observed that the phosphate is soluble in a soln. of ammonium carbonate, although G. C. Wittstein said that the phosphate does not dissolve in aq. soln. of ammonium salts. Observations were also made by E. A. Schneider. B. Lachowicz's experiments were made under similar conditions to those just indicated, and gave the following results :

Grams	H ₂ O	H ₂ O sat. CO ₂	NaHCO ₃	Na ₂ CO ₃	(NH ₄) ₂ CO ₃	Ca(HCO ₃) ₂	Na acetate
	—	—	4	5.046	2.284	1.132	6.476 per litre
P ₂ O ₅ dissolved	6.6	6.2	24.1	297.1	22.2	6.9	14.1 mgrms. per litre
Fe ₂ O ₃ dissolved	2.6	3.6	4.4	1.6	2.6	3.5	1.6 „ „

Here the salts are hydrolyzed, and the amount of phosphoric acid extracted from the ferric phosphate is much greater than is the case with water or neutral salt soln. This is also illustrated by the case of sodium hydrophosphate ; the effect is not that anticipated by the addition of a salt with a common ion, but rather that produced by a salt which hydrolyzes to form a base. This is in agreement with H. Rose's observation that ferric phosphate is immediately coloured reddish-brown by a soln. of potassium hydroxide, and the greater part of the phosphoric acid is extracted, but no ferric oxide is dissolved. Aq. ammonia behaves similarly provided no sodium phosphate forms a reddish-brown soln. with the phosphate. The ammoniacal soln. of ferric phosphate remains clear when mixed with potassium ferrocyanide, but the mixture yields prussian-blue when treated with an acid. According to J. W. Döbereiner, the salt can be separated from the ammoniacal soln. only when treated with an acid. J. B. Hester studied the base-exchange by ferric phosphate in soln. of different salts ; and S. Osugi and K. Saegi the effect of silicic acid on the solubility of ferric phosphate.

J. I. Pierre observed that 1 part of ferric phosphate dissolves in 12,500 parts of water sat. with carbon dioxide. B. Lachowicz observed that no appreciable effect on the solubility of ferric phosphate is produced by saturating the water with carbon dioxide, and this observation was confirmed by M. Gerlach who observed, further, that when calcium carbonate is mixed with either iron or aluminium phosphate in water, carbon dioxide causes an increased amount of calcium salt to pass into soln., without producing any perceptible effect on the amount of dissolved phosphoric acid. Observations were also made by M. von Wrangell and E. Koch. Calcium carbonate, and especially the hydrocarbonate, increases the solubility of ferric phosphate, and W. F. Sutherst added that while calcium carbonate has little or no influence, calcium hydroxide increases the solubility of iron and aluminium phosphates. H. J. Patterson also observed that the solubility of ferric phosphate is increased by lime. F. K. Cameron and J. M. Bell found that when 5 grms. of ferric phosphate are shaken for 5 days with 100 c.c. of :

Dissolved PO ₄	H ₂ O	H ₂ O sat. CO ₂	H ₂ O sat. CaSO ₄	H ₂ O sat. Ca(OH) ₂
	74	171	118	0 mgrms.

F. Ephraim and A. Schärer found that with gaseous hydrogen chloride, at room temp., a deliquescent addition product is formed ; and at 400°, anhydrous ferric phosphate forms a yellow powder containing about 5 mols. of HCl—it deliquesces in moist air, and is not changed by heating it to 300°. Hydrated ferric phosphate is easily soluble in dilute mineral acids, excepting phosphoric acid. R. F. Weinland and F. Ensgraber observed that, as with strengite, hydrated ferric phosphate is but slowly dissolved by nitric acid, but it is readily soluble in hydrochloric acid ; and G. Arth obtained a form which was said to be insoluble in nitric acid, but soluble in hot, conc. hydrochloric acid. A. Drevermann found that when ferric phosphate is heated with a soln. of alkali sulphide under press., iron sulphide and alkali phosphate are formed. P. Berthier showed that the freshly-precipitated salt is easily soluble in sulphuric acid, or in a soln. of ammonium sulphite, and at the same time the ferric is reduced to ferrous oxide ; and W. Wardlaw and co-workers showed that sulphur dioxide does not reduce ferric phosphate in conc. soln. of phosphoric acid.

H. Quantin observed that when ferric phosphate is heated in a current of carbon

tetrachloride, ferric chloride is formed. A. Naumann observed that ferric phosphate is insoluble in acetone. G. C. Wittstein said that ferric phosphate is insoluble in cold acetic acid; F. Sestini found that 100 c.c. of 10 per cent. acetic acid dissolves 0.007 grm. of the phosphate in the cold. The solubility of ferric phosphate in acetic acid was also discussed by G. Luff, and M. Gerlach. M. von Wrangell and E. Koch found that a litre of 0.02*N*-acetic acid dissolves 16.1 mgrms. B. Lachowicz's observations on the solvent action of sodium acetate are indicated above. T. S. Gladding, P. Cazeneuve and A. Nicolle, W. F. Sutherst, and E. Heydenreich found that the phosphate is easily soluble in tartaric and citric acids, and in the ammonium salts of these acids, and that it is also soluble in sodium citrate. J. Spiller also noted that the presence of sodium citrate prevented the precipitation of ferric phosphate. E. Erlenmeyer observed that a soln. of ammonium hydrocitrate of sp. gr. 1.09 dissolves 4.8 per cent. of P_2O_5 from hydrated ferric phosphate in 35 mins.; a soln. of ammonium citrate dissolves 5.8 per cent. P_2O_5 , and with an excess of ammonia, 21.2 per cent. is dissolved; whilst a 0.25 per cent. soln. of citric acid dissolves 17.5 per cent. P_2O_5 . M. Gerlach observed that oxalic acid is a more effective solvent than acetic acid; in the presence of an excess of ferric hydroxide the solvent action of oxalic acid was not affected, that of citric acid was lowered, and acetic acid did not dissolve a perceptible amount of phosphoric acid.

H. J. Patterson observed that the presence of organic matter favours the hydrolytic action of water on ferric phosphate. B. Lachowicz said that the presence of humic acid increases the solubility of iron phosphate. This is based on the fact that a soln. containing sodium hydrocarbonate or ammonium carbonate and humic acid will dissolve more phosphoric acid and ferric oxide than a soln. containing carbonate alone. The effect observed, however, may have been due to the presence of free bases resulting from the hydrolysis of the humates.

Ferric phosphate is soluble in an excess of soln. of ferric salts, including ferric acetate, but it is not soluble in a soln. of ferrous acetate. E. A. Schneider examined the soln. of ferric phosphate in one of ferric sulphate. Ferric phosphate is also dissolved to a considerable extent by a soln. of ammonium humate. W. Muthmann and H. Heramhof studied the use of ferric phosphate as an underglaze colour for pottery.

As just indicated, owing to the ready hydrolysis of normal ferric phosphate it might be anticipated that a number of basic salts would have found their way into the literature of chemistry as a legacy from the days when no method was known for distinguishing the false from the true. A. F. de Fourcroy and L. N. Vauquelin,² for example, said that a polybasic salt is formed when the normal phosphate is boiled with potash-lye. The reddish-brown powder is said to be fusible. C. F. Rammelsberg obtained a similar product; and G. C. Wittstein found that it is formed when a soln. of the normal phosphate in hydrochloric acid is treated with an excess of ammonia, and the product is washed and dried. It is said to be soluble in a soln. of ammonium tartrate, but insoluble in one of ammonium citrate, and, according to A. Millot, in ammonium oxalate. G. C. Wittstein represented it as **ferric oxyphosphate**, $2Fe_2O_3 \cdot P_2O_5 \cdot nH_2O$. C. F. Rammelsberg as $3Fe_2O_3 \cdot 2P_2O_5 \cdot nH_2O$; and A. Millot also regarded it as $3Fe_2O_3 \cdot 2P_2O_5 \cdot 8H_2O$. The equilibrium studies of S. R. Carter and N. H. Hartshorne, Figs. 691 and 692, do not show the existence of any such compound. Nature furnishes a few minerals which are basic salts, but that does not prove their existence as chemical individuals.

J. L. Jordan³ referred to a variety of Stahlstein, and J. C. Ullmann to a Grüneisenstein, which were called by A. Brogniart, *dufrénite*—after P. A. Dufrénoy. A. Breithaupt named a variety *kraurite*—from *κραῦρος*, harsh, or dry. The mineral has been found at Anglar, Haute Vienne; at Hirschberg, Westphalia; at Rochefort en Terre, France; at St. Benigna, Bohemia; at Wheal Phoenix, Cornwall; at Allentown, New Jersey; at Rockbridge Co., Virginia; etc. Analyses were

reported by C. J. B. Karsten, C. F. Rammelsberg, C. Diesterweg, F. Kurlbaum, E. Boricky, F. Kovar and F. Slavik, H. Laubmann, E. Kinch, E. Kinch and F. H. Butler, F. A. Massie, J. L. Campbell, A. Streng, F. W. Clarke, F. Pisani, L. N. Vauquelin, and A. H. Church. The results are somewhat vague. C. F. Rammelsberg considered that specimens free from ferrous salt are best represented as **ferric trihydroxyphosphate**, $2\text{Fe}_2\text{O}_3 \cdot \text{P}_2\text{O}_5 \cdot 3\text{H}_2\text{O}$, or $\text{Fe}_2(\text{PO}_4)(\text{OH})_3$. This can be taken as the best representative formula, and it is in agreement with F. Kovar and F. Slavik's results; A. Streng gave $\text{Fe}_5(\text{PO}_4)_3(\text{OH})_6$; and F. A. Massie gave $4\text{Fe}_2'''(\text{OH})_3\text{PO}_4 \cdot 3\text{Fe}_2''\text{P}_2\text{O}_7$, and E. Kinch, $\text{FeO} \cdot 3\text{Fe}_2\text{O}_3 \cdot 2\text{P}_2\text{O}_5 \cdot 6\text{H}_2\text{O}$.

The mineral is usually dull leek-green, olive-green, or greenish-black, and on exposure it alters to yellow or brown. The streak is siskin-green. The mineral usually occurs massive or in nodules, with a radiating fibrous structure, and drusy surface. The crystals are rare, and they are usually small and indistinct with the (001)-face rounded, and the (100)- and (010)-faces vertically striated. According to A. Streng, the rhombic crystals have the axial ratios $a : b : c = 0.8734 : 1 : 0.4262$. The (100)- and (010)-cleavages are indistinct. The crystals are pleochroic. The sp. gr. is 3.2 to 3.4—P. A. Dufrénoy gave 3.227. The hardness is 3.5 to 4.0. E. S. Larsen gave for the indices of refraction: $\alpha = 1.830$, $\beta = 1.840$, and $\gamma = 1.885$; and the optic axial angles: $2V = 36^\circ$ for Na-light, and 28° for red-light. Dufrénite is easily soluble in hydrochloric and sulphuric acids.

A dark brown mineral found at Visé, Belgium, was named *delvauxene*—after J. C. P. Delvaux—by A. H. Dumont, and *delvauxite*, by W. Haidinger. The analyses by A. H. Dumont, and J. C. P. Delvaux correspond with $2\text{Fe}_2\text{O}_3 \cdot \text{P}_2\text{O}_5 \cdot 24\text{H}_2\text{O}$. It was also examined by A. H. Church, V. Vesely, F. Ulrich, G. Cesaro, and A. Jorissen; and a similar mineral was found at Pisek, Bohemia, by C. Vrba. G. Cesaro found pseudomorphs after gypsum. The colour is dark brown, and the sp. gr. 1.85. F. Ulrich gave 1.716 for the index of refraction with Na-light. F. Cornu, and E. Dittler have shown that the mineral is colloidal.

The mineral **beraunite** obtained by A. Breithaupt⁴ from the vicinity of Beraun, Bohemia, has been also found in the Wheal Jane mine near Truro, Cornwall; and also at Scheibenberg, Saxony. It occurs in druses and in radiated, foliated aggregates, and as incrustations; it also occurs in monoclinic crystals. The analyses reported by C. F. Rammelsberg, G. Tschermak, H. Laubmann, E. T. Wherry, E. Boricky, A. Frenzel, and G. A. König correspond approximately with $3\text{Fe}_2\text{O}_3 \cdot 2\text{P}_2\text{O}_5 \cdot 8\text{H}_2\text{O}$, which P. Groth reduced to $\text{Fe}_3(\text{HO})_3(\text{PO}_4)_2 \cdot 2\frac{1}{2}\text{H}_2\text{O}$, or **ferric trihydroxydiphosphate**—possibly $\text{Fe}_2\text{PO}_4(\text{OH})_3$. G. Tschermak considered that beraunite is a product of the weathering of vivianite; and E. Boricky showed that it can also be produced from dufrénite. The mineral *eleonorite*, obtained by A. Nies from the Eleonore mine, near Giessen, was shown by A. Streng, and E. Bertrand to be identical with beraunite. The colour of beraunite is reddish-brown to dark hyacinth red, and the streak is brown. The mineral is strongly pleochroic. A. Streng gave for the axial ratios of the monoclinic crystals $a : b : c = 2.7538 : 1 : 4.0165$, and $\beta = 48^\circ 33'$. The habit of the small crystals is tabular parallel with (100), and the (100)-faces are striated parallel to the (100)/(001)-edge. Twinning occurs about the (100)-plane, and there are also penetration twins. The (100)-cleavage is distinct. G. Tschermak gave 2.95 for the sp. gr.; E. Boricky, 2.995; A. Frenzel, 2.983; and G. König, 2.940. The hardness is between 3 and 4. E. S. Larsen gave for eleonorite, $\alpha = 1.775$, $\beta = 1.786$, and $\gamma = 1.815$. The mineral is soluble in hydrochloric acid.

J. Steinman described a mineral from the vicinity of St. Benigna, Bohemia, and it has been found in a few other places; it was called *kakoxen*, which has been altered to **cacoxenite**. Analyses were reported by T. Thomson, C. von Hauer, A. Streng, A. H. Church, F. von Kobell, P. A. von Holger, C. C. von Leonhard, and E. Wittich and B. Neumann. Some analyses correspond with $2\text{Fe}_2\text{O}_3 \cdot \text{P}_2\text{O}_5 \cdot 12\text{H}_2\text{O}$; A. H. Church regarded it as a mixture of $2\text{FePO}_4 \cdot 3\text{H}_2\text{O}$, and $\text{Fe}_2\text{O}_3 \cdot 2\text{H}_2\text{O}$ with H_2O , and O. Mann also believed it to be a mixture. The mineral occurs in yellow or brownish-yellow, radiated tufts believed to be hexagonal. The sp. gr. given by A. Streng is 2.89, and E. Wittich and B. Neumann gave 2.816. The

hardness is 3 to 4. It becomes brown on exposure; and it is soluble in hydrochloric acid. H. Laubmann and H. Steinmetz observed that caxoxenite occurs in Bavaria, and another basic ferric phosphate which they called **xanthoxenite** occurs near Hübnerkobel, Bavaria.

A. Nies described a mineral which occurs amorphous, and in thin coatings in small stalactitic or spherical forms coloured dark brown. It was called **picite**, from its relationship to the picites resinacesis of A. Breithaupt. It occurs in a mine near Waldgirmes, Giessen. Analyses reported by A. Streng correspond with $8\text{FePO}_4 \cdot 6\text{Fe}(\text{OH})_3 \cdot 27\text{H}_2\text{O}$. A. Nies gave 2.83 for the sp. gr., and E. Boricky, 2.397. The hardness is between 3 and 4. F. Slavik said that picite is the same mineral as fouchérite—*vide infra*.

A number of acidic ferric phosphates has been reported. Some are formed by the action of conc. phosphoric acid on ferric phosphate. Thus, P. Hautefeuille and J. Margottet⁵ said that when a soln. of ferric oxide in glacial phosphoric acid is kept over 200° for some time, small crystals of **ferric triorthophosphate**, $\text{Fe}_2\text{O}_3 \cdot 3\text{P}_2\text{O}_5$, are produced. The dark reddish-brown crystals formed at 200° to 250° appear in short, channelled, rhombic prisms; from 250° to incipient redness, fusiform, triclinic crystals; and at a red-heat, long, monoclinic prisms. If the temp. of formation be 150° to 200° , the **tetrahydrate**, $\text{Fe}_2\text{O}_3 \cdot 3\text{P}_2\text{O}_5 \cdot 4\text{H}_2\text{O}$, is formed in pinkish, nacreous, rectangular lamellæ which are not readily attacked by water or alcohol. If the temp. of formation be 100° , pinkish, rhombic plates of the **hexahydrate**, $\text{Fe}_2\text{O}_3 \cdot 3\text{P}_2\text{O}_5 \cdot 6\text{H}_2\text{O}$, are formed—*vide infra*, the dihydrophosphate; and the metaphosphate. The hexahydrate was also prepared by E. Erlenmeyer in deliquescent crystals decomposed by water into the normal phosphate; and the work of S. R. Carter and N. H. Hartshorne, Fig. 692, shows the conditions of stability of this salt.

F. L. Winckler reported that crystals of **ferric diorthophosphate**, $\text{Fe}_2\text{O}_3 \cdot 2\text{P}_2\text{O}_5 \cdot 8\text{H}_2\text{O}$, or $\text{FeH}_3(\text{PO}_4)_2 \cdot 2\frac{1}{2}\text{H}_2\text{O}$, were produced when a soln. of ferric phosphate was kept in contact with phosphoric acid for a year in a closed vessel. The excess of phosphoric acid can be removed by washing with water. The cubic, pale rose-coloured crystals were found to be insoluble in water, but furnished a red soln. with aq. ammonia, and a light brown soln. with hydrochloric acid. A. Millot found that the salt is insoluble in acetic acid; but soluble in soln. of ammonium citrate, and alkali hydroxides or carbonates. E. Erlenmeyer, L. Dede, R. F. Weinland and F. Ensgraber, and A. Millot obtained the same **octohydrate**. A. Millot said that the anhydrous salt is prepared by fusing ferric oxide with an excess of phosphoric acid, and removing the excess by washing. If a high temp. is employed, part of the product becomes insoluble in acids, but its composition is the same—*vide infra*, the dihydrophosphate. S. R. Carter and N. H. Hartshorne observed the conditions of equilibrium of the octohydrate, and also of the **decahydrate**, $\text{Fe}_2\text{O}_3 \cdot 2\text{P}_2\text{O}_5 \cdot 10\text{H}_2\text{O}$.

E. Erlenmeyer added that if a mol of hydrated ferric oxide be dissolved in 14 mols of H_3PO_4 as 48 per cent. phosphoric acid, and the product be treated with 21 times its vol. of cold water, a greyish-yellow precipitate is formed of the composition: $6\text{Fe}_2\text{O}_3 \cdot 7\text{P}_2\text{O}_5 \cdot 3\text{H}_2\text{O}$, and when this is treated with boiling water, $8\text{Fe}_2\text{O}_3 \cdot 9\text{P}_2\text{O}_5 \cdot 3\text{H}_2\text{O}$ is formed, whilst the filtrate, when boiled, furnishes $4\text{Fe}_2\text{O}_3 \cdot 5\text{P}_2\text{O}_5 \cdot 3\text{H}_2\text{O}$. If alcohol be used instead of water, the white precipitate has the composition: $8\text{Fe}_2\text{O}_3 \cdot 11\text{P}_2\text{O}_5 \cdot 9\text{H}_2\text{O}$. C. F. Rammelsberg obtained the salt, $2\text{Fe}_2\text{O}_3 \cdot 3\text{P}_2\text{O}_5 \cdot 8\text{H}_2\text{O}$, in cubic crystals from a sat. soln. of the normal salt in phosphoric acid; and A. Millot, by adding water to the filtrate from $\text{Fe}_2\text{O}_3 \cdot 2\text{P}_2\text{O}_5 \cdot 8\text{H}_2\text{O}$, or by heating a soln. of ferric sulphate and ammonium dihydrophosphate. E. Erlenmeyer boiled iron with an excess of phosphoric acid, and obtained a pink powder of the composition: $4\text{Fe}_2\text{O}_3 \cdot 7\text{P}_2\text{O}_5 \cdot 9\text{H}_2\text{O}$; and he also prepared $2\text{Fe}_2\text{O}_3 \cdot 5\text{P}_2\text{O}_5 \cdot 17\text{H}_2\text{O}$, and added that a large number of compounds appear to exist between the di- and triorthophosphates. If it would serve any useful purpose, the formulæ can be arranged to make these products appear as mixed hydrophosphates. S. R. Carter and N. H. Hartshorne observed only three acidic ferric phosphates in their study of the system $\text{Fe}_2\text{O}_3\text{--P}_2\text{O}_5\text{--H}_2\text{O}$.

L. Dede found that the addition of phosphoric acid soln. to a ferric chloride soln. results in a considerable increase in the sp. conductivity of the soln.; the latter also increases rapidly with the further addition of the acid soln. and reaches a constant value when equivalent amounts of salt and acid are mixed. This is assumed to be due to the formation of the complex **trichlorophosphatoferric acid**,

$[\text{Cl}_3\text{Fe}(\text{PO}_4)]\text{H}_3$. This complex acid could not be isolated; the same remark applies to its salts. A further addition of the phosphoric acid soln., whilst having no appreciable effect on the conductivity, resulted in the replacement of the three chlorine atoms of the complex by another phosphato-group, *i.e.* **diphosphatoferrous acid**; this was isolated and analyzed; it corresponds with $[\text{Fe}(\text{PO}_4)_2]\text{H}_3 + 2\frac{1}{2}\text{H}_2\text{O}$. The complex is very stable.

According to E. Erlenmeyer,⁶ when ferric oxide is dissolved in phosphoric acid until a precipitate begins to appear, and the soln. is then evaporated to dryness, and the excess of phosphoric acid washed out with ether, the pink, crystalline powder is **ferric dihydrophosphate**, $\text{Fe}(\text{H}_2\text{PO}_4)_3$. When treated with an excess of cold water it yields a yellow powder of the composition: $8\text{Fe}_2\text{O}_3 \cdot 9\text{Fe}_2\text{O}_5 \cdot 3\text{H}_2\text{O}$; and with boiling water it yields normal ferric phosphate. The acidic salt: $\text{Fe}_2\text{O}_3 \cdot 3\text{P}_2\text{O}_5 \cdot 6\text{H}_2\text{O}$, is equivalent to this salt; whilst $\text{Fe}_2\text{O}_3 \cdot 2\text{P}_2\text{O}_5 \cdot 8\text{H}_2\text{O}$, is equivalent to $2\text{Fe}(\text{OH})(\text{H}_2\text{PO}_4) \cdot 5\text{H}_2\text{O}$. Observations were made by R. F. Weinland and F. Ensgraber, and S. R. Carter and N. H. Hartshorne—*vide* Fig. 692; P. Hautefeuille and J. Margottet also prepared the salt in pale rose-coloured, rhombic plates. The *dihydrate*, $\text{Fe}(\text{H}_2\text{PO}_4)_3 \cdot 2\text{H}_2\text{O}$, was obtained by S. R. Carter and N. H. Hartshorne.

J. W. Döbereiner⁷ observed that ferric phosphate forms a brown soln. with aq. ammonia; and, according to L. J. Cohen, when a large excess of ammonium hydrophosphate is added to a strongly acidic soln. of ferric chloride, a white precipitate of **ammonium ferric phosphate**, $\text{NH}_4\text{H}_2\text{PO}_4 \cdot \text{FePO}_4$, is produced. When the salt is repeatedly washed with water, it is partially hydrolyzed, and a brownish-yellow basic residue is formed. If alcohol be added to an ammoniacal soln. of the double salt, a brown gelatinous precipitate, $2(\text{NH}_4)_2\text{HPO}_4 \cdot 3\text{FePO}_4 \cdot 3\text{Fe}(\text{OH})_3$, is produced. R. F. Weinland and F. Ensgraber prepared **ferric ammonophosphate**, $[\text{Fe}(\text{PO}_4)_2\text{H}_3]_3\text{NH}_3 \cdot 7\text{H}_2\text{O}$, in pink, microscopic hexagonal plates, from a mixture of 35 grms. of 85 per cent. phosphoric acid, 56 grms. of a soln. of ferric chloride (10 per cent. Fe), with a soln. of 53.5 grms. of ammonium chloride in 210 grms. of water, but allowing it to stand 6 months at ordinary temp. They also prepared the *pyridine salt*, $\text{Fe}(\text{PO}_4)_2\text{H}_3 \cdot \text{C}_6\text{H}_5\text{N}$. By heating on a water-bath for a prolonged period, a soln. of hydrated ferric oxide in phosphoric acid and sodium hydroxide, pale pink crystals of **sodium ferric diorthophosphate**, $\text{NaH}_2\text{Fe}(\text{PO}_4)_2 \cdot \text{H}_2\text{O}$, are formed. This *monohydrate* gradually passes to the *trihydrate* in moist air. If a mixture of sodium chloride or phosphate and a soln. of hydrated ferric oxide in phosphoric acid is heated on a water-bath for some time, a pale pink, crystalline powder of **sodium ferric triorthophosphate**, $\text{NaH}_2[\text{Fe}(\text{PO}_4)_3] \cdot \text{H}_2\text{O}$, is produced. It is sparingly soluble in water. L. Ouvrard obtained by fusion the phosphate, $3\text{Na}_2\text{O} \cdot 2\text{Fe}_2\text{O}_3 \cdot 3\text{P}_2\text{O}_5$, which is decomposed by water; and similarly the **potassium ferric phosphate**, $3\text{K}_2\text{O} \cdot 2\text{Fe}_2\text{O}_3 \cdot 3\text{P}_2\text{O}_5$, which is not attacked by boiling water, and $\text{K}_2\text{O} \cdot \text{Fe}_2\text{O}_3 \cdot 2\text{P}_2\text{O}_5$, which is insoluble in water, and but slightly attacked by acids.

A bright green mineral was observed by J. C. Ullmann⁸ on the dufrénite at Sayn, Westphalia, and he called it *Chalkosiderit*, *i.e.* **chalcosiderite**. The same mineral was found on the andrewsite of the West Phoenix mine, Cornwall. The analysis corresponds with **copper ferric oxyphosphate**, $\text{CuO} \cdot 3\text{Fe}_2\text{O}_3 \cdot 2\text{P}_2\text{O}_5 \cdot 8\text{H}_2\text{O}$. The colour is siskin-green, and the streak pale green. The individual crystals are small, with prismatic faces, and in sheaf-like aggregates. The triclinic crystals have the axial ratios $a : b : c = 0.7910 : 1 : 0.6051$, and $\alpha = 92^\circ 58'$, $\beta = 93^\circ 29\frac{3}{4}'$, and $\gamma = 107^\circ 41'$. The (011)-cleavage is easy; the sp. gr. is 3.108; and the hardness, 4.5. E. S. Larsen gave for the indices of refraction, $\alpha = 1.733$ to 1.775, $\beta = 1.840$, and $\gamma = 1.844$ to 1.845. Another Cornish mineral is closely related with chalcosiderite; it was called **andrewsite** by N. S. Maskelyne; the composition approximates $5\text{Fe}_2\text{O}_3 \cdot \text{P}_2\text{O}_5 \cdot 5\text{H}_2\text{O}$, and it has 10 to 11 per cent. of copper oxide. The bluish-green, globular masses have a radiated structure, a blackish-green streak; a sp. gr. of 3.475; and a hardness of 4.

A mineral from Leoben, Styria, was called by C. von Hauer ⁹ *delvauxene*; a specimen from Nenacovic, Bohemia, was described by E. Boricky, and called **borickite** by J. D. Dana. Analyses by C. von Hauer, and E. Boricky correspond with **calcium ferric oxyphosphate**; J. Vala and R. Helmhacker gave the formula: $2\text{CaO} \cdot 0.5\text{Fe}_2\text{O}_3 \cdot 2\text{P}_2\text{O}_5 \cdot 16\text{H}_2\text{O}$. C. von Hauer found that the freshly-obtained mineral, on exposure to a damp atmosphere, for:

	3	4	5	8	12 days
Gain in weight . . .	10.06	0.36	0.12	0.23	0.01 per cent.

When the mineral is dried over calcium chloride, it loses 8.14 per cent. in 2 days, and 8.88 per cent. in 3 days. Borickite is a reddish-brown mineral gel. It occurs compact, or in reniform masses without cleavage; the sp. gr. is 2.696 to 2.707; and the hardness between 3 and 4. E. S. Larsen gave 1.57 to 1.67 for the mean refractive index. Borickite is soluble in hydrochloric acid.

J. R. Blum ¹⁰ described a mineral occurring in nodules in the clays of Battenberg, Rhenish Bavaria. The mineral was called **calcioferrite**. The analysis corresponds with a calcium ferric oxyphosphate, $\text{Ca}_3\text{Fe}_2(\text{PO}_4)_4 \cdot \text{Fe}(\text{OH})_3 \cdot 8\text{H}_2\text{O}$. The nodules or foliated masses are sulphur-yellow, greenish-yellow, siskin-yellow, or yellowish-white. The streak is sulphur-yellow. The crystal system is thought to be monoclinic. The cleavage is perfect or foliated in one direction. The sp. gr. is 2.523 to 2.529; and the hardness 2.5. A. Breithaupt ¹¹ described a mineral from Schneeberg, Saxony, and Hirschberg, Westphalia, and he called it **globosite**. The analysis shows that it is a magnesium calcium ferric oxyphosphate. It occurs in wasp-yellow or yellowish-grey, globular concentrations. The sp. gr. is 2.825 to 2.827; and the hardness, 5.0 to 5.5. It is slowly soluble in hydrochloric acid. D. Guimaraes described a mineral of the wagnerite family, corresponding with $4\text{R}_2'\text{PO}_4 \cdot 9\text{R}_3''(\text{PO}_4)_2$, which he called **arrojadite**. It is dark green, and monoclinic, with colourless to light green pleochroism. It is biaxially negative, and has the refractive index $\gamma = 1.70$, and $\gamma - \alpha = 0.007$. The hardness is greater than 5.

V. R. von Zepharovich ¹² obtained a mineral from Cerhovic, Bohemia, and he called it **barrandite**. Analyses reported by V. R. von Zepharovich, E. V. Shannon, and A. Lacroix correspond with **aluminium ferric oxyphosphate**, $(\text{Fe}, \text{Al})_2\text{O}_3 \cdot \text{P}_2\text{O}_5 \cdot 4\text{H}_2\text{O}$, or $(\text{Al}, \text{Fe})\text{PO}_4 \cdot 2\text{H}_2\text{O}$, or, according to E. V. Shannon, $\text{H}_2\text{Fe}(\text{PO}_5) \cdot \text{H}_2\text{O}$. Barrandite occurs in spheroidal concretions which are indistinctly radiated and fibrous; the surface may be angular, and the structure concentric. The colour is pale bluish-, reddish-, greenish-, or yellowish-grey; and the streak greenish- to bluish-white. The sp. gr. is 2.576; the hardness, 4.5—E. V. Shannon said 2. The mean index of refraction, given by V. R. von Zepharovich, is 1.57 to 1.58—E. V. Shannon gave 1.650, and for the birefringence, 0.020; E. S. Larsen gave 0.02 for the birefringence and 1.640 for the mean refractive index. It is slowly soluble in boiling hydrochloric acid. F. Brandt described **harborite**, $6(\text{Al}, \text{Fe})_2\text{O}_3 \cdot 4\text{P}_2\text{O}_5 \cdot 17\text{H}_2\text{O}$, as a mineral occurring near Maranhao, Brazil. The octahedral crystals have a sp. gr. of 2.781 to 2.798; hardness of 5.0 to 5.5; and index of refraction, between 1.602 and 1.618. H. Laubmann and H. Steinmetz, ¹³ and F. Sellner described a ferric aluminium phosphate at Kreuzberg, and Königswart, and it was named **kreuzbergite**, $(\text{Al}, \text{Fe})_2\text{O}_3 \cdot \text{P}_2\text{O}_5 \cdot n\text{H}_2\text{O}$. According to H. Laubmann and H. Steinmetz, kreuzbergite occurs in rhombic crystals with $a:b:c = 0.3938:1:0.5261$ —F. Sellner gave $0.42234:1:0.56194$ —its refractive index is 1.62; its birefringence 0.02 to 0.025; its sp. gr. 2.135. There is also **alumochalcosiderite**, $\text{CuAl}_2\text{Fe}_4(\text{PO}_4)_4(\text{OH})_5 \cdot 5\text{H}_2\text{O}$, from Shenckenstein, described by A. Jahn and E. Gruner.

A brownish-red, amorphous mineral from Fouchère, France, was described by A. Lacroix ¹⁴ and called **fouchèrite**—*vide* picite. Its hardness is about 3.5; and it is easily soluble in hydrochloric acid. The analysis corresponds with a **calcium aluminium ferric oxyphosphate**, $\text{Ca}_3(\text{Fe}, \text{Al})_4(\text{PO}_4)_8 \cdot 8(\text{Fe}, \text{Al})(\text{OH})_2 \cdot 22\text{H}_2\text{O}$.

H. Berman and F. A. Gonyer ¹⁵ described a mineral **landesite**, $3\text{Fe}_2\text{O}_3 \cdot 20\text{MnO} \cdot 8\text{P}_2\text{O}_5 \cdot 27\text{H}_2\text{O}$, *vide* manganese phosphates, 12. 64, 26. E. S. Simpson described a white, hydrated potassium aluminium ferric phosphate, $\text{K}_2(\text{Fe}, \text{Al})_7(\text{OH})_{11}(\text{PO}_4)_4 \cdot 6\text{H}_2\text{O}$, which he called **leucophosphate**. It is birefringent, and has a sp. gr. 2.30 to 2.65; it is insoluble in water, but soluble in conc. hydrochloric acid.

For the *manganous ferric phosphates*, *vide* manganese phosphate, 12. 64, 26.

W. T. Schaller ¹⁶ reported a hydrated **manganous ferric phosphate**, $2\text{MnO} \cdot \text{Fe}_2\text{O}_3 \cdot 4\text{P}_2\text{O}_5 \cdot 14\text{H}_2\text{O}$, to occur as a buff-coloured mineral at Pala, California. He called it **salmonsite**—after F. A. Salmon. It occurs in cleavable, fibrous masses of sp. gr. 2.85, and refractive indices $\alpha = 1.655$, $\beta = 1.660$, and $\gamma = 1.665$. The optical axial angle $2V$ is very large. The pleochroism is α = colourless, β yellow, γ orange-yellow. E. S. Larsen gave the refractive indices $\alpha = 1.655$, $\beta = 1.66$, and $\gamma = 1.670$.

W. T. Schaller found, at Pala California, masses of a dark brown mineral which he called **sicklerite**—after the Sickler family of Pala. Its composition corresponds with a **lithium manganous ferric phosphate**, $6\text{MnO} \cdot 3(\text{Li}, \text{H})_2\text{O} \cdot \text{Fe}_2\text{O}_3 \cdot 4\text{P}_2\text{O}_5 \cdot \text{H}_2\text{O}$. The mineral was taken to be rhombic; the sp. gr. is 3.0; the indices of refraction $\alpha=1.715$, $\beta=1.735$, and $\gamma=1.745$. The optical character is negative, and the pleochroism ranges from yellow to orange-red. E. S. Larsen gave for the indices of a variety from Utah, $\omega=1.743$ and $\epsilon=1.830$.

S. L. Penfield described a mineral from Grafton, New Hampshire, and he called it **grafftonite**. Its composition approximates $(\text{Fe}, \text{Mn}, \text{Ca})_3(\text{PO}_4)_2$. It furnishes indistinct monoclinic crystals with lamellar intergrowths of darker-coloured triphylite. The colour is pale salmon-pink when fresh, but this becomes darker on exposure to air. Grafftonite is related to heterosite—*vide* 12. 64, 27. W. T. Schaller proposed to reserve the term heterosite for ferric phosphate and retain purpurite for manganic phosphate; but this suggestion has not been adopted. The axial ratios $a : b : c = 0.886 : 1 : 0.582$, and $\beta = 66^\circ$. The sp. gr. is 3.672, and the hardness, 5. H. Berman gave for the indices of refraction $\alpha=1.704$, $\beta=1.706$, and $\gamma=1.725$. The optical character is positive, the optic axial angle $2V=50^\circ$; and the dispersion is fairly strong. The mineral readily dissolves in hydrochloric acid.

G. Cesaro and G. Desprez¹⁷ described a mineral from Richelle, Belgium, which they called **richellite**. The analysis corresponds with **calcium ferric fluophosphate**, although G. Cesaro gave $8\text{Fe}(\text{PO}_4) \cdot \text{Fe}_2\text{OF}_2 \cdot (\text{OH})_2 \cdot 36\text{H}_2\text{O}$ for the formula. There was also present 5.76 to 7.19 per cent. of calcium oxide. It is yellow, and massive, compact, or foliated. The sp. gr. is 2.0, and the hardness 2 to 3. It is readily soluble in acids.

A. Breithaupt¹⁸ described a yellow or yellowish-brown mineral from the alum shales of Gräfenenthal, and Saafeld, Thuringia, which was called **diadochite**—from *διάδοχος*, a successor, alluding to the hypothesis that it is an iron sinter where phosphorus has replaced the arsenic. A related mineral from Argenteau, Belgium, was called by H. Forir and A. Jorissen, *destinezite*—after M. Destineze. The analyses reported by C. F. Rammelsberg, and A. Carnot, correspond with **ferric sulphatophosphate**, $7\text{Fe}_2\text{O}_3 \cdot 6\text{SO}_3 \cdot 3\text{P}_2\text{O}_5 \cdot 12\text{H}_2\text{O}$; and G. Cesaro gave for destinezite, $2\text{Fe}_2\text{O}_3 \cdot 2\text{SO}_3 \cdot \text{P}_2\text{O}_5 \cdot 12\text{H}_2\text{O}$. The mineral occurs in reniform or stalactitic masses with a curved, lamellar structure; or else in microscopic, six-sided plates belonging to the monoclinic system. The colour is yellow or yellowish-brown. The sp. gr. is 2.035 to 2.220; and the hardness, 3. It is soluble in hydrochloric acid. F. Ulrich gave 1.815 to 1.999 for the sp. gr., 2.5 for the hardness, and 1.706 for the index of refraction for Na-light.

There is a mineral called **corkite** by M. Adam,¹⁹ since it came from the Glenoore mine, Cork, in Ireland; *dernbachite*, since it came from Dernbach in Nassau; and the name *beudantite* was applied by A. Lévy to the mineral from Horhausen. The analyses of F. Sandberger, C. F. Rammelsberg, and J. Percy correspond approximately with the doubtful formula: $\text{PbSO}_4 \cdot \text{FePO}_4 \cdot 2\text{Fe}(\text{OH})_3$. The colour is dark olive-green, yellowish-green, black, or brown. The crystals are usually opaque, seldom transparent; they are usually acute rhombohedra, sometimes square rhombohedra. The crystals belong to the rhombohedral system, and, according to H. Dauber, have the axial ratio $a : c = 1 : 1.1842$. The (0001)-cleavage is easy; the sp. gr. 4.0 to 4.3; and the hardness 3.5 to 4.5. E. S. Larsen gave for the mean refractive index 1.930. The optical character is negative.

A. Schwarzenberg²⁰ obtained **ferric pyrophosphate**, $\text{Fe}_4(\text{P}_2\text{O}_7)_3$, by treating a soln. of ferric chloride with ordinary sodium phosphate, if sodium pyrophosphate is employed, normal ferric phosphate is produced, although W. E. Ridenour reported that ferric pyrophosphate can be so prepared. According to A. Schwarzenberg, ferric pyrophosphate is a soluble powder with a yellow tinge which deepens at 100° , but becomes paler again on cooling. L. A. Welo found the magnetic susceptibility to be 20.7×10^{-6} mass unit. According to A. Schwarzenberg, ferric pyrophosphate is soluble in acids, in a soln. of sodium phosphate, of ferric chloride, of ammonium carbonate, of ammonium citrate, and in aq. ammonia; but it is

insoluble in cold hydrochloric acid, acetic acid, sulphurous acid, and in soln. of ammonium chloride. If the salt be dissolved in hot hydrochloric acid, and the soln. treated with ammonia, a precipitate of a soluble form of the pyrophosphate is obtained which is soluble in acids. J. H. Gladstone also prepared the insoluble form of the pyrophosphate; and H. Timpe, a colloidal soln. with alkali carbonate as peptizing agent. H. N. Holmes and R. E. Rindfusz also obtained a red colloidal soln. with ammonium as peptizing agent. E. Oliveri-Mandala found that ferric pyrophosphate at 30°—anhydrous and enneahydrate—dissolves in $\text{Na}_4\text{P}_2\text{O}_7$ in the fixed ratio, $\text{Na}_4\text{P}_2\text{O}_7 : \text{Fe}_4(\text{P}_2\text{O}_7)_3 = 3 : 1$. Expressing concentrations in mols per litre, at 30.4° :

$\text{Na}_4\text{P}_2\text{O}_7$.	.	0.14	0.20	0.26	0.32	0.38
$\text{Fe}_4(\text{P}_2\text{O}_7)_3$	{	Anhydrous	0.047	0.068	0.088	0.108	0.124
		Enneahydrate	0.050	0.072	0.094	0.114	0.134

P. Pascal found for the solubility of ferric pyrophosphate in aq. ammonia at 0°, when the concentrations are expressed per 100 grms. of sat. soln. :

NH_3	.	0.884	1.59	3.71	4.72	5.92	8.26	10.55	15.96	18.83
$\text{Fe}_4(\text{P}_2\text{O}_7)_3$.	5.606	9.75	14.85	15.94	14.71	13.89	7.40	2.52	0.445

E. C. Franklin and C. A. Kraus found that the pyrophosphate is insoluble in liquid ammonia; and W. H. Krug and K. P. McElroy, that it is insoluble in acetone. E. Oliveri-Mandala found that the solubility of ferric pyrophosphate in aq. soln. of sodium citrate, at 28°, when the concentrations are expressed in mols per litre, is as follows :

Na citrate	.	.	0.2004	0.3951	0.4760	0.5289	0.6355
$\text{Fe}_4(\text{P}_2\text{O}_7)_3$.	.	0.1712	0.3160	0.3704	0.4037	0.4572

T. Fleitmann and W. Henneberg, C. N. Pahl, P. Pascal, J. Persoz, and H. Rose noted that the fresh precipitate is soluble in an excess of the precipitant, owing to the formation of a sodium ferric salt. E. Oliveri-Mandala said that at 30.3°, the solubility of ferric pyrophosphate, S mols per litre of the sat. soln., in a soln. of sodium pyrophosphate, is as follows :

$\text{Na}_4\text{P}_2\text{O}_7$.	.	0.1895	0.2106	0.2835	0.3938	mol per litre
S	.	.	0.0676	0.0741	0.0990	0.1365	

H. A. Spoehr and J. H. C. Smith, and E. F. Degering and co-workers studied the catalytic oxidation of carbohydrates and related compounds, and E. J. Theriault and co-workers, that of glucose, by ferric pyrophosphate. If ferric pyrophosphate be heated with two-thirds its weight of syrupy phosphoric acid and acetone for 12 hrs. at 50°, P. Pascal, and R. F. Weinland and F. Ensgraber observed that **ferric hydropyrophosphate**, $\text{H}_6[\text{Fe}_2(\text{P}_2\text{O}_7)_3] \cdot 7\text{H}_2\text{O}$, is formed. P. Hautefeuille and J. Margottet said that the *hydrate*, $\text{Fe}_2(\text{H}_2\text{P}_2\text{O}_7)_3 \cdot \text{H}_2\text{O}$, or $\text{Fe}_2\text{O}_3 \cdot 3\text{P}_2\text{O}_5 \cdot 4\text{H}_2\text{O}$, is formed by rapidly heating to 150° to 200° a soln. of phosphoric acid saturated with ferric hydroxide—about 15 per cent. $\text{Fe}(\text{OH})_3$ is required. The pale rose-red crystals are rectangular, lustrous, doubly-refracting plates which can be freed from adherent phosphoric acid by washing.

According to P. Pascal, the solubility of ferric pyrophosphate in a soln. of sodium pyrophosphate is due to the formation of a complex salt, **sodium ferric pyrophosphate**, $3\text{Na}_4\text{P}_2\text{O}_7 \cdot \text{Fe}_4(\text{P}_2\text{O}_7)_3 \cdot 9\text{H}_2\text{O}$, or $\text{Na}_6\text{Fe}_2(\text{P}_2\text{O}_7)_3 \cdot 9\text{H}_2\text{O}$, and he suggested that the salts should be called *ferripyrophosphates*, analogous to the ferricyanides. The *enneahydrate*, $\text{Na}_6\text{Fe}_2(\text{P}_2\text{O}_7)_3 \cdot 9\text{H}_2\text{O}$, is slowly deposited from a 15 per cent. soln. of sodium pyrophosphate sat. with ferric pyrophosphate at 30°. The salt appears as a pale violet, microcrystalline powder.

S. Freed and C. Kasper discussed the complex ion $[\text{Fe}_2(\text{P}_2\text{O}_7)_3]^{''''''}$, A. Rosenheim and T. Triantaphyllides obtained P. Pascal's salt, $\text{Na}_6\text{Fe}_2(\text{P}_2\text{O}_7)_3 \cdot 9\text{H}_2\text{O}$, as well as a pale grey salt, $\text{Na}_3\text{Fe}_4(\text{P}_2\text{O}_7)_5 \cdot 28\text{H}_2\text{O}$, corresponding with the salt described below. C. N. Pahl also prepared the last-named salt, as well as $5\text{Na}_4\text{P}_2\text{O}_7 \cdot \text{Fe}_4(\text{P}_2\text{O}_7)_3 \cdot 7\text{H}_2\text{O}$.

A. Rosenheim obtained $\text{Na}_3[\text{Fe}(\text{OH})_2\text{P}_2\text{O}_7]\cdot 4\text{H}_2\text{O}$; E. Oliveri-Mandala showed that C. N. Pahl's formula for the last-named salt is wrong; it should be $3\text{Na}_4\text{P}_2\text{O}_7\cdot\text{Fe}_4(\text{P}_2\text{O}_7)_3\cdot 14\text{H}_2\text{O}$. It is best prepared by saturating a soln. of sodium pyrophosphate with moist ferric pyrophosphate, by mechanical agitation; the dissolution of the calculated amount of sodium pyrophosphate in a soln. of ferric chloride of sp. gr. 1.280 to 1.282, followed by the precipitation of the double salt by alcohol gives a product contaminated with sodium chloride, and in the presence of sodium chloride the solubility determinations are too low. Ferric pyrophosphate dissolves in soln. of sodium pyrophosphate always in the proportion $\text{Fe}_4(\text{P}_2\text{O}_7)_3\cdot 3\text{Na}_4\text{P}_2\text{O}_7$, independently of the concentration of the soln. Thus, expressing concentrations in mols per litre, aq. soln. of sodium citrate containing 0.3456, 0.4760, and 0.5374 mols of sodium citrate per litre, at 26.5° , dissolve respectively 0.0186, 0.0249, and 0.0269 mols of $3\text{Na}_4\text{P}_2\text{O}_7\cdot\text{Fe}_4(\text{P}_2\text{O}_7)_3$ per litre; and with soln. of sodium chloride:

NaCl	.	.	.	0.0	0.01	0.02	0.03	0.04	0.05	0.06
$\text{Na}_{12}\text{Fe}_4(\text{P}_2\text{O}_7)_6$	{	30°	.	0.0100	0.0077	0.0053	0.0037	0.0028	0.0023	0.0020
		50.5°	.	0.062	0.039	0.023	0.015	0.011	0.009	0.009

According to S. M. Jörgensen, when a mixture of microcosmic salt and ferric oxide is melted in a platinum dish over a Bunsen flame, and the resulting brown glass is treated with dil. hydrochloric acid to wash out the sodium phosphate, a bluish, pearly, crystalline mass of sodium ferric pyrophosphate, NaFeP_2O_7 , is formed in rhombic plates, and in prisms terminated by acute pyramids. The salt is decomposed by fusion with sodium carbonate; by boiling, conc. sulphuric acid; whilst conc. hydrochloric or nitric acids have scarcely any action on the salt.
